Clustering of Atherogenic Behaviors in Coffee Drinkers

Elizabeth M. Puccio, MD, Janice B. McPhillips, MS, Elizabeth Barrett-Connor, MD,
and Theodore G. Ganiats, MD

Abstract: We studied the clustering of coffee consumption and selected atherogenic behaviors in older adults living in a southern California community. Men were somewhat more likely to drink caffeinated coffee while women were more likely to drink decaffeinated coffee. In men, but not women, caffeinated coffee drinking decreased with age and decaffeinated coffee drinking increased. Caffeinated coffee drinkers drank more alcohol, consumed more dietary saturated fats and cholesterol, were more likely to be current smokers and less likely to be current exercisers than were non-coffee drinkers. Smoking and exercise also showed a dose-response relationship to the amount of caffeinated coffee consumed. Risk factor levels among drinkers of decaffeinated coffee were more like those of caffeinated coffee than non-drinkers. These data illustrate the clustering of atherogenic behaviors with coffee drinking and highlight their potential importance in interpreting the growing body of literature about coffee and health. (*Am J Public Health* 1990; 80:1310–1313).

Introduction

Whether coffee drinking is a risk factor for coronary heart disease continues to be controversial. Some epidemiologic evidence has linked heavy coffee consumption to elevations in total serum cholesterol or low density lipoprotein cholesterol,[1–3] suggesting a mechanism for the association of coffee and coronary heart disease. Several investigators have reported an increased risk of coronary heart disease morbidity and mortality with heavy coffee intake,[4–8] but others have questioned whether this association is independent of cigarette smoking.[9–12] Only two previous studies[13,14] have examined coffee use in relation to multiple behaviors other than smoking, that could themselves be associated with hyperlipidemia and/or coronary heart disease. In this paper, the coffee drinking habits of a southern California population-based cohort of older men and women were examined in relation to multiple putative heart disease risk factors to determine the extent to which coffee drinking is associated with other atherogenic behaviors.

Methods

Participants were a part of the Rancho Bernardo Heart and Chronic Disease Study, a population-based study designed to examine lifestyle and chronic disease patterns in older adults. All surviving members of the cohort who were between 40 and 84 years of age when first seen in 1972-74 were invited to participate in 1984-87, and 80 percent did so. Height and weight were measured with participants in light clothing without shoes; obesity was estimated using body mass index (kg/m^2). Data on current exercise habits, current and past smoking history, current alcohol consumption, hours of nightly sleep, and use of non-contraceptive estrogens (women only) were determined by a standardized interview administered by trained personnel. Coffee intake and diet data were ascertained as part of a self-administered food frequency questionnaire. Participants were asked to estimate their average consumption of decaffeinated and regular coffee (in cups per day) and their usual intake (as an adult over 45 years of age) of 128 food items.

A crude index of dietary saturated fat and cholesterol intake was made based upon reported consumption of foods selected by the American Heart Association as food to limit in a fat-controlled, low-cholesterol diet.[15] Six responses for frequency of intake ranging from "never" to "daily" were transformed to ranks from "1" to "6" with "1" corresponding to "never" and "6" corresponding to "daily." The cholesterol and saturated fat index was created by computing an integer sum of the participants' coded estimates of consumption for the following 12 foods or food categories: beef, ham, hot dogs, eggs, milk, organ meats, cream, cheese, ice cream, butter, lard, dessert cakes.

Participants were grouped into four coffee drinking categories: those who drank no coffee, drinkers of caffeinated coffee only, drinkers of decaffeinated coffee only, or those who drank both caffeinated and decaffeinated coffee. Participants were also grouped according to whether or not they reported exercising at least three times a week, whether they currently smoked cigarettes, quit smoking, or never smoked, and for female participants, whether or not they reported having taken any oral estrogen within the past two weeks. The total number of bottles or cans of beer, glasses of wine, highballs, cocktails, mixed drinks, liqueurs or other alcoholic drinks consumed was used as an index of alcohol consumption; daily alcohol intake estimated from the past week or from usual intake from the diet questionnaire were nearly identical and only the former is shown. Reported hours of usual nightly sleep were estimated to the nearest hour.

Results are presented for 2,304 men and women ages 50-89. One-way analysis of covariance was used to compare mean age-adjusted risk factor levels among those who drank caffeinated coffee only, decaffeinated coffee only, or both caffeinated and decaffeinated coffee to those who drank no coffee. In addition, mean risk factors for caffeinated coffee drinkers were compared to decaffeinated coffee drinkers. Age-adjusted rates of categorical risk factors were computed by the direct method and differences in age-adjusted rates were tested using the Mantel-Haenszel summary chi-square with one degree of freedom. No adjustments were made to account for the effects of multiple comparisons.

Coffee consumption in those who drank caffeinated coffee only (464 men, 514 women) was divided into three categories as follows: one to two cups per day, three to four cups per day, and

five or more cups per day. Trends in age-adjusted behavioral risk factor with increasing coffee consumption were tested by analysis of covariance for continuous variables and by the Mantel extension test[16] for categorical variables. Because there were very few heavy drinkers of decaffeinated coffee only, analysis of trends could not be performed.

Results

As shown in Table 1, the 1,028 men and 1,276 women ages 50-89 years were similar with regard to the proportion who drank no coffee (11 percent) or caffeinated and decaffeinated coffee combined (28 percent). Men were somewhat more likely to drink caffeinated coffee only and women to drink decaffeinated coffee only, although both sex differences were small. The proportion of men who drank only decaffeinated coffee increased with age (p for trend <0.001) while the proportion who drank only caffeinated decreased (p for trend = 0.002); similar trends were not observed in women.

Mean age and sex-adjusted behaviorial risk factors for coronary heart disease (CHD) by coffee consumption category are summarized in Table 2. In both men and women, caffeinated coffee drinkers were significantly more likely to be current cigarette smokers and to consume more alcohol and saturated fats and cholesterol than non-coffee drinkers. The percent of women who exercised at least three times per week was lower in all types of coffee drinkers as compared to non-coffee drinkers; the reverse was true for men (data not shown). Neither difference was statistically significant. BMI and hours of nightly sleep did not differ significantly in coffee drinkers as compared to non-drinkers in either sex.

Age-adjusted levels of many risk factors among decaffeinated coffee drinkers were more similar to those who drank caffeinated coffee than to those who drank no coffee (Table 2). However, dietary consumption of saturated fats and cholesterol was significantly higher in caffeinated coffee drinkers as compared to decaffeinated coffee drinkers in both men and women. Women who drank caffeinated coffee had a significantly lower use of replacement estrogen than decaffeinated coffee drinkers (data not shown). Drinkers of caffeinated coffee consumed more alcohol and were more likely to be current cigarette smokers than those who drank decaffeinated coffee.

Among those who drank caffeinated coffee only, the proportion of men and women who currently smoke cigarettes increased with increasing caffeinated coffee consumption (p for trend in age-adjusted rates <0.01 for men, <0.001 for women) (Table 3). The frequency of current exercise decreased with increasing coffee consumption in both men and women although the trend was significant only among men. There were no other clear associations between the amount of coffee consumed and alcohol, dietary cholesterol, hours of nightly sleep, or post-menopausal estrogen use (among women only). The range of decaffeinated coffee drinking (one to two cups) was too narrow to be considered in a similar analysis.

Discussion

Coffee drinking may be a marker for an atherogenic diet, cigarette smoking, or sedentary lifestyle, rather than an etiologic factor in heart disease outcomes. For example, Hennekens, *et al.*,[10] reported a positive association between coffee drinking and mortality from coronary heart disease, independent of cigarette smoking, that disappeared with adjustment for daily alcohol consumption, level of physical activity, and use of coffee additives.

In the present study, there was an increased occurrence of three habits in caffeinated coffee drinkers: use of cigarettes, excess consumption of alcohol, and an atherogenic diet. There was a dose-response relationship in the extent to which some of these behaviors were practiced among drinkers of caffeinated coffee.

These results support the findings of Jacobsen and Thelle,[13] Haffner, *et al.*,[14] and others[17],[*] who found that coffee drinkers consume a more atherogenic diet than their non-coffee drinking counterparts. Carmody, *et al.*,[18] also reported that smokers and ex-smokers were more likely than non-smokers to drink greater amounts of alcohol and coffee; most individuals who reported drinking more alcohol also reported drinking more coffee, regardless of smoking habit. In a study of an industrial population, Phillips, *et al.*,[19] noted that smokers drank an average of 1.5 to 2 more cups of coffee per day and drank more alcohol weekly than non-smokers.

Others have reported that coffee drinkers have a decreased body mass relative to non-coffee drinkers.[20] In this cohort, body mass index did not differ by coffee intake, but those who drank five or more cups of caffeinated coffee per day exercised significantly less than those who drank less. Leon, *et al.*,[21] found that the use of caffeine-containing

beverages, particularly coffee, showed a negative correlation with treadmill exercise capacity which persisted after cigarette smoking and other variables were partitioned out.

Coffee consumption could be an important link in the association between hours of nightly sleep and mortality. Karacan, *et al.*,[22] reported sleep disturbances in coffee drinkers while several other investigations of health-related practices have addressed the association between reported hours of nightly sleep and subsequent all cause mortality.[23–26] In this cohort, hours of nightly sleep were no different in coffee drinkers compared to non-drinkers and sleep hours did not vary with amount of caffeinated coffee consumed in either men or women. It is possible that older adults who found that caffeinated coffee disturbed their sleep patterns had discontinued its use.

In this cohort, 44 percent of men and 49 percent of women drank at least one cup of decaffeinated coffee per day. Behavior patterns in those who drank only decaffeinated coffee were more similar like those of caffeinated coffee drinkers than non-coffee drinkers. These findings suggest that decaffeinated coffee consumption should be considered in studies of the relationship beween coffee drinking and disease whenever a significant proportion of the study population drinks decaffeinated coffee.

In this study, coffee drinking was determined at the same time as all other behaviors, although the period of use for different behaviors varied from current to usual. Others have shown that current diet is a strong predictor of past or usual diet,[27] and we have found a strong correlation between usual and recent alcohol intake in this cohort. It seems unlikely that differences in the period of use explain the observed associations, unless one postulates that drinkers of coffee (with or without caffeine) have a better memory for unhealthy behavior than non-drinkers.

The diet data reported here were not directly validated; we know of no way to confirm dietary fat and saturated/unsaturated fat ratios short of direct observation or a fat biopsy.[28] Indirect validation of both food frequency and 24-hour diet recall was obtained in this cohort by demonstrating expected diet-disease associations. We have reported the expected cross-sectional associations of sodium, calcium, and potassium with blood pressure,[29,30] and inverse associations of fiber with heart attack;[31] potassium with stroke[32] and calcium with hip fracture in prospective studies.[33] Other attributes were also indirectly validated: smoking was inversely associated with HDL and directly with waist-hip-ratio;[34] alcohol was associated directly with waist-hip-ratio, aspartate aminotransferase and HDL;[35] exercise was positively associated with HDL and inversely associated with obesity, pulse rate, and plasma insulin.[36] Any misclassification of self-reported behaviors would be expected to reduce these associations, and not have caused them.

Because caffeinated and decaffeinated coffee consumption were both associated with more atherogenic behaviors, studies which seek to demonstrate the relationship between coffee consumption and morbidity or mortality must consider these other potential behavioral risk factors in the coffee-disease association. The concordance of heavy coffee intake with several lifestyles known to be related to heart disease risk implies a high level of potential confoundng in studies linking coffee consumption to hyperlipidemia and/or coronary heart disease.

Validation of Mothers' Reports of Dietary Intake by Four to Seven Year-Old Children

CHARLES E. BASCH, PHD, STEVEN SHEA, MD, REBECCA ARLISS, PHD, ISOBEL R. CONTENTO, PHD, JILL RIPS, MPHIL,
BERNARD GUTIN, PHD, MATILDE IRIGOYEN, MD, AND PATRICIA ZYBERT, PHD

Abstract: The validity of mothers' recall of four to seven year-old children's diet was assessed among 46 first generation Latino immigrant families from the Dominican Republic by comparing intake recalled by the mother to unobtrusive home observations of children. Correlations were moderate to high for calories and for most nutrients. There were no differences in mean intake of total calories or in intake of most macronutrients and micronutrients assessed. At least two-thirds of the children in the lowest (or highest) quintile based on home observation were correctly classified into the lowest or second lowest (or highest) quintiles based on mother's reports for calories and most nutrients. For all food items that were both observed and reported, 51 percent of reported portion sizes were equivalent to observed portion sizes, 15.5 percent were smaller, and 33.5 percent were larger. There was fair to good agreement on the number of food items eaten, with the exception of vegetables. Mothers' recall appears to be useful for classifying children by intake of calories, macronutrients and micronutrients, but provides a somewhat less accurate measure of actual foods eaten, portion sizes, and nutrient levels consumed. (*Am J Public Health* 1990; 80:1314–1317.)

Introduction

Valid measurement of diet is essential to improve understanding of the role of diet in the etiology of diseases and for evaluating dietary interventions. The 24-hour dietary recall is probably the most widely used instrument in surveys and studies of food intake in the United States,[1–7] and its validity has been investigated in adults by comparison with weighed intakes,[8,9] direct observation,[10–12] and other dietary measurement methods.[13–15] Two recently published studies[16,17] have reported on the validity of recall by adults who cook and serve children's meals, usually mothers. No studies of this kind have been conducted in Latino families with young children or have used unobtrusive observation of children in their homes as a validation criterion. Nor have any previous studies assessed the validity of parental recall of children's nutrient intake using regression methods to adjust for caloric intake, permitting estimation of nutrient values that remove the effect of caloric intake.

We assessed the validity of mothers' recall of four to seven year-old children's dietary intake of total calories and 17 nutrients and of portion sizes and food items aggregated within food groups among first generation Latino immigrant families from the Dominican Republic by comparing intake recalled by the mother to unobtrusive home observations of children.

Methods

Subjects and Setting

Subjects were drawn from a sample of four to seven year-old children and their mothers participating in the Columbia University Study of Childhood Activity and Nutrition, a longitudinal study of young children. The total sample comprises families residing in a primarily Latino, densely populated, low-income neighborhood in northern Manhattan, New York City. Eligibility required that children be generally healthy with no special dietary prescriptions or restrictions.

A total of 46 Dominican families (mean age of children = 5.4 years, S.D. = 0.8) participated in the validation study. There were 18 males (mean age = 5.0 years, S.D. = 0.78 years) and 28 females (mean age = 5.7 years, S.D. = 0.78 years). All parents in the validation study were mothers (mean age = 33.8 years, S.D. = 4.6). Thirty-one of the children lived in single parent families.

Measurements

Home observation: Home observations were conducted between May 1987 and May 1989 by trained observers, fluent in Spanish, on the day before a regularly scheduled study visit in which the mother was to report her child's dietary intake for the preceding 24-hour period. The time period of the home observation ensured observation of the main meal (usually 4:00pm to 8:00pm). Parents were told that the observer was interested in the child's activities but were not informed about the specific aims of the study.

The observer followed the child and recorded the foods the child ate, the amounts, and the time. When necessary the observer asked the child's mother what the child was eating. Prior to data collection, observers were trained and tested in visually estimating portion sizes. Data were recorded on an instrument adapted from the Health and Nutrition Examination Survey.[7]

Twenty-four hour dietary recall: Different individuals conducted the interviews and home observations. On the day following the home observation the mother was asked to describe the food items eaten by the child during each eating occasion, the time of day, and portion sizes. Three dimensional food models, food packages, glasses, cups, spoons, and other utensils, and questions about food preparation methods and brand names of foods were used to increase accuracy. The sections of the recall corresponding to the time when the observer was present in the home were excerpted for analysis. For both observed dietary intake and 24-hour recall data, foods and portion sizes were converted to nutrient intakes using a dietary analysis program,[18] which used published nutrient data from the United States Depart-

ment of Agriculture.[19,20] Supplemental nutrient values were obtained from other sources.[21]

Statistical Analysis

Nutrient intake values were adjusted for average caloric intake using regression techniques.[22] The natural logarithm transformation was used to improve normality for intake of nutrients but untransformed values are reported in the tables. Nutrient analyses were also performed using unadjusted values. Results were the same and only adjusted values are reported. Pearson product-moment correlation coefficients were used to estimate consistency between observed and reported calorie and nutrient intake. Paired t-tests were used to evaluate differences between means. We also examined the proportion of children correctly classified into quintiles of nutrient intake.[22] Consistency between observed and reported portion size was calculated within nine food groups comprising the 200 food items that were both observed and reported. Portion sizes were defined as equivalent if they were within one and one-half times the smaller amounts. The proportions of mothers who reported fewer, the same, or more items than observed within food groups were calculated, and the Z test[23] was used to assess differences in proportions.

Results

Correlations were moderate to high for most nutrients, although mean nutrient intakes derived from mothers' reports tended to be higher than those derived from observations (Table 1). Paired t-tests indicated no significant differences for total calories or macronutrients, except protein. For micronutrients, there were differences for cholesterol, calcium, iron, thiamine, riboflavin, and niacin. At least two-thirds of the children in the lowest quintile based on home observation were correctly classified into the lowest or second lowest quintiles based on mother's reports for all 17 nutrients except carbohydrates, calcium, and riboflavin (Table 2). Fewer children were correctly classified into the highest two quintiles for fats and cholesterol. For micronutrients, mother's reports were about as good as or better at high levels of intake than they were at low levels of intake. For all nutrients, mean observed intake in the highest quintile was at least three times as high as that in the lowest quintile, so that correct classification has practical significance.

Overall, for all 200 food items that were both observed and reported, 51 percent of reported portion sizes were equivalent to observed portion sizes, 15.5 percent were smaller, and 33.5 percent were larger (Table 3). When mothers made errors in reporting portion sizes they tended to overestimate for all food groups except butter/fats/oils. For all foods combined the proportion underestimated was significantly lower than the proportion over-estimated. The small numbers of dairy products (n = 4) and eggs consumed (n = 1) precluded meaningful analysis for these food groups.

There was fair to good agreement on the number of food items eaten, with the exception of vegetables (Table 4). In all nine food groups mothers tended to report fewer items eaten than observed. The practical significance of the percent agreement depends in part on the overall frequency of consumption. The proportion of mothers who agreed with the observer that items were not eaten is thus included in Table 4. For nine out of 10 of the most frequently eaten foods, observed and reported frequencies were identical (data not shown).

Discussion

Ability to measure children's absolute nutrient intake (e.g., 300 milligrams of cholesterol per day) as well as macronutrient intake as a proportion of absolute calories is important since some nutritional guidelines are stated in these terms.[24–26] Adjustment for caloric intake is necessary when assessing the association between particular nutrients and disease risk or the causal role of nutrients in disease processes.[27–29] The regression method of adjustment recommended by Willett and used in this study[22] permits the estimation of nutrient values while removing the effect of total caloric intake. This is not achieved by dividing nutrient values by total caloric intake.[30]

TABLE 1—Means, standard deviations (SD), Pearson correlation coefficients, and 95 percent confidence intervals for observed and reported nutrients and calories (data based on reports from 46 Dominican mothers residing in Northern Manhattan and corresponding home observations of children's diet, 1987–1989)*

Vegetables	30.4	41.3	28.3	17.4

Our findings support the utility of mother's recall of children's diet for research needing accurate classification of subjects' nutrient intake according to an ordinal or interval level of measurement. The differences in mean levels of intake for protein and several of the micronutrient values raise concerns about the use of parental recall for testing differences in mean nutrient intake between groups. Our results also indicate substantial errors in estimating portion sizes of foods, particularly over-estimation, as well as overreporting and underreporting of specific food items, and thus raise questions about the use of mother's recall as a method of measuring these aspects of children's eating behavior. Studies that require precise and accurate estimates of mean nutrient intake within groups or descriptions of food items and portion sizes consumed may need to rely on direct observation.

The dietary variable of interest in chronic disease epidemiology is typical diet. Eating patterns vary by time of week and year,[31–33] so that a single 24-hour dietary recall will not represent typical diet. Mothers' recall of children's evening meal may differ from that of other meals, and the presence of the observer may influence mothers' menu for the day or her likelihood of remembering what she served. The main evening meal is important, however, as evidenced by the observed consumption of calories, fat and saturated fat, as well as other nutrients.

Results from this study are consistent in some respects with other reports of the utility of surrogate-reported dietary information. The studies in adults, which reached guarded conclusions about the utility of this strategy, assumed that subjects' reports were accurate and these reports were the criterion against which the surrogates' reports were tested.[34–36] A trained observer provided the criterion measure in our study. Klesges, *et al*,[16] performed home observations of 30 children ranging in age from 24 to 48 months in which the observer weighed and recorded all food eaten by the child during the day. Dietary recalls were taken from the parent later that same day. At the nutrient level findings were similar to those in our study. At the food level, Klesges, *et al*, found that parents made errors in estimating portion sizes but correctly recalled 96 percent of the food items the child ate, a level of accuracy higher than in our study. Collecting recall data from the parents on the same day as the observation, rather than on the day following the home observation (which is how the recall method is generally used), or having the observer weigh food prior to consumption by the child may have enhanced the accuracy of reporting.

Eck, *et al*,[17] conducted unobtrusive observations of 34 children four to nine years of age eating a single meal in a cafeteria with both of their parents. Dietary recalls were taken from family members individually and as a group on the following day. There were no significant differences between observed and reported mean intake of total calories, calories from total fat, protein, carbohydrates, or sugar, or in intake of cholesterol, sodium, iron or calcium. The mean correlation for these nutrients was 0.77 for fathers, 0.63 for mothers, and 0.86 for the mother, father and child as a group. Eck, *et al*, also examined overreporting and underreporting of nutrients by food groups and reported that while general agreement was high, over- and underreporting varied greatly. The correlations between reported and observed nutrient intakes were, in general, higher than in our study. This study was based on a single meal in a cafeteria setting eaten by middle to high socioeconomic status families,[17] while our study was done in the home of Latino subjects of lower educational attainment.

Our study, together with the investigations by Klesges, *et al*, and Eck, *et al*, indicate that mothers' reports of children's diet appear to be useful to measure children's intake of calories, macronutrients, and micronutrients. The recall gives a somewhat less accurate measure of actual foods eaten, portion sizes, and nutrient levels consumed. Additional research is needed to verify our results in other Latino subgroups and non-Latino populations, to improve understanding about factors that improve and impede mother's reports about children's diet, and to test strategies to improve the validity of these measures.

Development and Validation of a Food Use Checklist for Evaluation of Community Nutrition Interventions

Alan R. Kristal, DrPH, Barbara F. Abrams, DrPH, RD, Mark D. Thornquist, PhD, Loreli DiSogra, EdD, Robert T. Croyle, PhD, Ann L. Shattuck, MS, RD, and Holly J. Henry, MS, RD

Abstract: We developed a new dietary assessment instrument, the Food Behavior Checklist (FBC), which measures food use related to adopting lower-fat and higher-fiber diets. The FBC is a simplification of the 24-hour diet recall that consists of 19 simple yes/no questions about foods consumed during the previous day. To develop the FBC, an expert committee generated a list of foods based on our intervention program, and we used focus groups and random-digit dialing pretests to refine the format and clarify items. To validate the FBC, we compared responses of 96 women on the FBC to information collected during a professionally administered 24-hour diet recall. For most items, agreement between the FBC and 24-hour recall, based on the kappa statistic, was good to excellent. Agreement was poor for items requiring detailed knowledge about food composition (e.g. high-fiber cereal). There was a trend to over-report general food categories (e.g. luncheon meats) but not specific food items (e.g. ice cream). In an embedded randomized study, we found that a set of introductory items designed to serve as a memory retrieval cue did not improve agreement between the FBC and 24-hour recall. These data provide preliminary evidence supporting the use of short checklist questionnaires on the previous day's food use as a means to assess diet at the group or community level. This relatively inexpensive and rapid measure can be used to inform the design of public health nutrition programs and as an evaluation tool in intervention research. (*Am J Public Health* 1990; 80:1318–1322.)

Introduction

There is an emerging consensus that dietary change interventions are a necessary component of public health programs to prevent cardiovascular diseases and cancer.[1] Although the details of recommendations differ, the principal dietary goals shared by leading American public health organizations[1–3] are to: 1) reduce fat intake from approximately 37 to 30 percent or less of total calories; and 2) increase the intake of nutrient- and fiber-rich fruits and vegetables from approximately two to five or more servings per day. Much recent research has focused on community-level interventions, such as mass media campaigns and supermarket programs, because public health professionals believe that these interventions will be the most cost-effecitve means to change dietary behavior.[4]

Both the design and evaluation of public health nutrition intervention programs have problems in assessing dietary behavior in target communities. Standard diet assessment instruments used for clinical and etiological research such as multiple-day diet records and food frequency questionnaires are lengthy, expensive, and difficult to administer to representative population samples. Even the 24-hour recall, the traditional survey interview method used to assess group-level dietary intake,[5] is problematic in community intervention research; it takes approximately 30 minutes to complete, it is sufficiently complex to require both professionally trained interviewers and rigorous standardization and analysis procedures, and it is expensive to administer, code, and analyze. Clearly, new approaches to dietary assessment are needed.

Research on dietary assessment methods appropriate for community-level nutrition intervention research has focused on three approaches. The first approach is based on ecological-level measures: supermarket warehouse orders,[6] supermarket sales,[7] supermarket characteristics (such as percent of meat cases offering chicken, turkey, and fish[8]) and cafeteria receipts.[9] A second approach is based on short dietary questionnaires designed to assess only a limited number of nutrients.[10,11] A third approach is based on questionnaires that assess only the dietary behavior targeted by the intervention program. Several examples of these instruments have been described, for example the MRFIT fat counter,[12] but little is known about the statistical characteristics of these measures when used as program evaluation tools.

In this report we describe a new instrument to assess group-level dietary behavior that is based on the approach of assessing specific target behavior, the Food Behavior Checklist (FBC). The FBC is a simplification of the 24-hour recall, consisting of simple yes/no questions about foods consumed in the previous day. It focuses on a recent and defined time period and may thus reflect more accurately true food use compared to recall of perceived "usual" diet.[13] The advantage of the FBC over the traditional 24-hour recall is that the FBC can be administered quickly by non-professional personnel, needs no coding before analysis, can be completed over the telephone, and can be easily tailored to a specific intervention program. It was developed originally as a component of the evaluation of the Nutrition and Cancer Prevention Program of the California Department of Health Services. The FBC was subsequently incorporated into the evaluation of the Kaiser Family Foundation's Community Health Promotion Grants Program.* Here we describe the instrument, its development, and a study to evaluate its validity.

Methods

Development of the Questionnaire

The goal of the Nutrition and Cancer Prevention Program is to change the consumption of foods which are

believed to contribute to the development of cancer—to increase the use of foods containing protective nutrients (vitamin C, carotenoids, and dietary fiber) and decrease the use of foods high in fat. The program goals were operationalized as: increasing the consumption of fruits, vegetables, whole grain/high fiber products and reduced-fat milk, and decreasing the consumption of full-fat dairy products, fried foods, ground beef and other high-fat meats, pastries, cakes, ice cream, and butter or margarine on bread and vegetables. We used these intervention goals to generate a list of foods for inclusion in the FBC.

The draft FBC was reviewed by an expert panel, including epidemiologists, nutritionists, a statistician, and a cognitive psychologist. A series of pre-tests was completed over the telephone, using respondents from a broad range of socioeconomic and age groups. Based on the results of these steps, an introductory section asking the respondent to recall which meals and snacks were consumed the previous day was added, several items were eliminated, and the questionnaire was reworded and reordered.

We then used focus groups to examine the relevance of the instrument to different ethnic groups (Black, Hispanic and Asian) and to men as well as women. The questionnaire was again reworded, and several ethnically specific foods were added as descriptions to the original food behavior items. Finally, we completed a full-scale, random-digit dial pilot survey of 299 adult residents of two California communities. From this pilot we compiled a final interviewer manual and code book (available from the authors) and completed minor rewording. The 19 items included in the instrument are given in the Appendix.

Validation Study

Detailed descriptions of the sampling scheme, participant demographic characteristics, and dietary assessment methods used in this study have been published.[11,14] Briefly, participants were 96 women ages 45 through 59 years who were members of a large health maintenance organization in Western Washington State. Dietary assessments included two, four-day diet records (at study entry and six months later) and a food frequency questionnaire (two months after study entry). Participants received no information about nutrition or their diets until all data were collected.

The validity study was completed by telephone three months after study entry. The interview consisted of: the FBC; a four-minute set of questions on usual dietary behavior; and a detailed, standardized 24-hour recall administered by a research nutritionist (HH or AS). The FBC used in the validation study differed slightly from the final FBC because pretesting had not yet been completed. These differences are given in the Appendix. The 24-hour recall was administered by working the participant through their previous day, using prompts to obtain a complete list of foods and asking questions to get specific information (brand of cereal, type of bread, etc). Nutritionists defined a high-fiber cereal as one with at least 3g of dietary fiber per serving; whole grain breads included all breads with the exception of white breads and caramel-colored breads made without whole grain flour. We considered this 24-hour recall to be a good criterion measure of foods eaten in the previous day because 24-hour recalls are the most commonly used method to obtain short-term, retrospective data on dietary intake.[5]

We also considered whether the use of introductory questions on the context of the previous day's food consumption would improve the validity of responses to the FBC. Studies of human memory have shown that context can serve as an effective retrieval cue for memories of personal events.[15] Furthermore, studies of survey respondents indicate that many persons first think about the circumstances surrounding a health event when they are asked to specify its date or frequency.[16] This suggests that specific, incidental events such as eating a bowl of cereal may be better remembered if the individual first thinks of the more easily remembered context such as having breakfast. Study participants were thus randomized into two groups: receiving or not receiving five introductory questions before beginning the FBC. These introductory questions were similar to probes used during a 24-hour recall, and asked about whether the participant ate breakfast, lunch, and dinner, whether they ate in a restaurant and, if so, in what type of restaurant (fast food/other).

Statistical Methods

We used two approaches to measure agreement between the FBC and the criterion measure, the 24-hour recall.

- The first approach was to compare the proportion of participants who reported each food behavior from the FBC to the proportion reporting the same behavior during the 24-hour recall. This comparison considers whether FBC and 24-hour recall would yield different community-level estimates of dietary behavior practiced in the previous day. We calculated confidence intervals around these differences using the exact binomial distribution.[17]
- The second approach to assess validity was to examine the proportion of individuals with the same responses from the FBC and the 24-hour recall. This analysis considers whether the FBC and 24-hour recall differ when measuring the behavior of individuals. We used the kappa statistic to assess agreement in this application.[18] In presenting the results, we indicated items for which expected chance agreement was over 90 percent because the kappa statistic in this case will be based on very few discordant pairs and thus be highly unreliable.[19]

Finally, we examined the association of items on the FBC with usual percent of energy from fat and usual fiber intake. To characterize usual dietary intake in these analyses we used the average of values from the food frequency questionnaire and eight days of diet records. We did not expect that all items on the FBC would be strongly associated with usual dietary intake because the use of a food in the previous day is not a reliable measure of usual food use.[5] However, we considered associations of FBC items with usual dietary intake as evidence of the content validity of the instrument.

Results

Table 1 gives the proportion of participants reporting use of 18 foods in the previous day from both the FBC and the 24-hour recall. Overall, the proportion of yes responses tended to be higher for the FBC than the 24-hour recall (sign test $p < 0.01$), although the 95 percent confidence intervals for these differences excluded zero for only five items: high-fiber cereal, fruit, a vegetable at lunch, a vegetable at dinner, and whole-grain bread. The percent of concordant responses and the corresponding kappa statistic for each item are also given in Table 1. Observed agreement was under 85 percent for only three items: high-fiber cereal; whole-grain breads; and butter or margarine on bread. Only two kappas, for high-fiber cereal and bacon or sausage, were under 0.60,

TABLE 1—Agreement between Food Behavior Checklist and 24-Hour Recall

Food Behavior Checklist Item*	Responded Yes: Food Behavior Checklist (%)	Responded Yes: 24-Hour Recall (%)	95 Percent Confidence Interval for Difference	Agreement: (%)	Agreement: Kappa
Cereal	50.0	50.0	(−1.9, 1.9)	97.9	0.96
High-fiber cereal	89.1	65.2	(12.0, 23.9)	76.1	0.37
Pastry	13.5	9.4	(0.0, 4.2)	95.8	0.80
Bacon or sausage	3.1	4.2	(−3.0, 2.3)	96.9	0.56**
Milk	65.3	65.3	(−0.2, 0.2)	91.6	0.81
Fruit	90.5	84.2	(1.2, 6.3)	93.7	0.72
Salad	52.1	45.8	(−6.8, 10.2)	85.4	0.71
Vegetable at lunch	34.4	24.7	(0.0, 13.1)	86.0	0.67
Vegetable at dinner	68.4	53.7	(8.7, 14.7)	85.3	0.70
Butter on vegetable	19.0	12.6	(−3.9, 9.6)	89.5	0.61
Dark bread	56.3	45.8	(2.4, 14.9)	83.3	0.67
Muffins	17.7	15.6	(−3.5, 6.5)	91.7	0.70
Butter on bread	37.5	33.3	(−4.9, 10.7)	83.3	0.64
Fried food	7.3	7.3	(−1.9, 1.9)	97.9	0.85
Cold cuts	6.3	6.3	(−2.3, 2.3)	95.8	0.64
Ground beef	13.5	13.5	(−2.3, 2.3)	95.8	0.82
Cakes	45.8	45.8	(−2.3, 2.3)	95.8	0.92
Ice Cream	14.6	14.6	(−1.9, 1.9)	97.9	0.92

**Expected chance agreement >90%.
N = 96

a level that may be considered a cutpoint for fair agreement beyond chance. For the remaining 16 items, agreement was very good to excellent for 11 (kappa > 0.80) and good for five (kappa > 0.60).

In further analysis stratified by whether or not participants received the introductory questions to the FBC, there was no evidence that introductory questions improved the quality of responses (data available from the authors). The tendency for a higher proportion of participants to report food use in the FBC than in the 24-hour recall remained evident in both strata. This bias was not smaller among participants who received the introductory questions, nor was there a trend for kappas to be higher.

The associations of usual dietary intakes of fat and fiber (assessed from a food frequency and eight days of dietary records) with responses to the FBC are given in Table 2. With only a single exception (vegetable at dinner) the direction of association was consistent with the fat or fiber content of each food. Confidence intervals for differences in percent of energy from fat excluded zero for consumption of pastry, salad, butter or margarine on breads, and cold cut luncheon meats. Confidence intervals for fiber intake excluded zero for only cereal and fruit. These results did not differ when food use in the previous day was taken from the 24-hour recall.

Discussion

Overall, reports of previous day's food behavior related to fat and fiber intake appeared similar when assessed by either the Food Behavior Checklist or a 24-hour recall. There

was a general trend for overreporting food use on the FBC, but this did not appear to be a bias to report more socially desirable behavior. Both desirable (e.g. "vegetable at dinner" and "high-fiber cereal") and undesirable (e.g. "butter or margarine on bread" or "breakfast or snack pastry") behavior were reported more frequently on the FBC than the 24-hour recall.

We suspect that forward telescoping,[20] a term used in cognitive psychology to describe recall of a past event as more recent in time, may explain higher responses from the FBC. In this study, we observed telescoping for common or non-specific dietary behavior, such as vegetable and fruit eating; responses to more specific dietary behavior, such as use of cold cuts or ice cream, were identical from the FBC and 24-hour recall. This suggests that a checklist approach to dietary assessment should emphasize specific rather than general dietary behavior. For example, it may be better to read a list of specific vegetables or to ask "What vegetables did you eat with lunch" rather than to ask simply "Did you eat a vegetable with lunch?"

From a cognitive perspective, the FBC has a number of advantages over more complex instruments to assess dietary behavior. First, the question format is straightforward. This feature reduces variation in interviewer behavior and simplifies the response task of the participant.[21] Second, participants do not appear to find remembering the previous day's food behavior difficult. Finally, the use of a 24-hour period provides the respondent with a simple landmark. For questions on specific dietary behavior this may have reduced the telescoping errors typical of more long-term recall periods.[22]

There was also evidence that questions requiring high levels of nutritional knowledge did not produce valid data. For the questions on high-fiber cereal and whole-grain bread we determined that the source of disagreement between the FBC and 24-hour recall was due to the nutritionists' correct classification of the food based on brand name information obtained during the 24-hour recall. For example, participants may report that they are eating a high-fiber cereal when, based on published nutrient composition data, a serving of the cereal actually contained less than 3 grams of fiber per serving. In the final FBC, the "high-fiber" cereal question was modified to a list of specific high fiber cereals, eliminating the need for the respondent to know the fiber content of cereals they ate.

We had hypothesized that the introductory questions would serve as a memory retrieval cue and improve the accuracy and speed of responses. Contrary to our expectations, interviews with the five simple, introductory questions took an average of 1.4 additional minutes to complete ($p < 0.01$) and resulted in no meaningful improvements in agreement between the FBC and 24-hour recall. These results suggest that the FBC items did not pose a significant challenge to respondents' memory abilities.

Given the characteristics of participants in this study there are limits to generalizing these results to more representative population samples. Participants in this study were all women, interested in diet and health, well educated, and willing to comply with intensive measurement protocols. Evaluation of the FBC in other populations is now under investigation. The FBC has been used successfully during baseline assessments of 15 communities in the Kaiser Family Foundation's Community Health Promotion Grants Program, and we have found strong community-level associations between the FBC and measures of supermarket characteristics.[23] The FBC has also been incorporated into an ongoing random-digit dial health survey of Washington State residents, and validation studies from this survey are underway.

Data collected from the FBC lend themselves to two types of analyses. When data are collected at the beginning of a planned intervention, they can be used to document problems and formulate program goals. When data from an FBC are collected pre- and post-program implementation in intervention and control communities, they can be used to evaluate changes in the prevalence of food use attributable to an intervention program. Thus, if intervention program goals can be clearly formulated as increases or decreases in the prevalence of use of specific foods, the FBC may be a superior instrument to standard dietary questionnaires which attempt to measure total intake of nutrients.

In conclusion, there is preliminary evidence that a checklist questionnaire is a reasonable approach to community-level dietary assessment. We have demonstrated that a careful process of selecting questionnaire items can produce an instrument with both face and content validity, and answers to a checklist questionnaire are similar to those obtained from a 24-hour recall. The FBC may be an inexpensive and technically simple dietary assessment tool when group-level data on dietary behavior can be used to evaluate intervention programs or monitor dietary change.

APPENDIX

Food Items Included in Food Behavior Checklist

Cereal (hot or cold)
    a. If yes, was it a high fiber cereal?*
        a. If yes, was it any of the following? Any bran cereal, Raisin Bran, Wheatena, Shredded Wheat, Oatbran, Oatmeal or Fruit n Fiber?**
Breakfast or snack pastry such as donuts, croissants, danish, coffee cake, or sweet rolls, pan dulce or custard tarts
Bacon, sausage, or chorizo
Milk, including milk on cereal, chocolate milk, or cafe con leche
    a. If yes, was it**
        regular or whole milk?
        low-fat or 2% milk?
        skim, 1% or non-fat milk?
One or more servings of fresh fruit
Green salad
Vegetable, other than salad, at lunch
Vegetable, other than salad, at dinner
Butter, margarine, or creamy sauce on cooked vegetables
Dark bread, including whole wheat, rye, or pumpernickel
Whole grain or bran muffins
Butter or margarine on bread
Deep-fried food like french fried potatoes, fried chicken or fish, tacos, egg rolls, or dim-sum
Hot dog, salami, bologna, or other luncheon meat
Hamburger, meat loaf, tacos or other dish with ground beef
Cake, pie, custard, tart or cookies
Ice cream

Food and Nutrient Intake Differences between Smokers and Non-smokers in the US

Amy F. Subar, PhD, RD, Linda C. Harlan, PhD, and Margaret E. Mattson, PhD

Abstract: Data from the Second National Health and Nutrition Examination Survey were analyzed to determine food and nutrient intake differences between current smokers (also categorized as light, moderate, and heavy smokers) and non-smokers. Smokers in several age-race-sex categories have lower intakes of vitamin C, folate, fiber, and vitamin A than non-smokers, and intake tended to decrease as cigarette consumption increased, particularly for vitamin C, fiber, and folate. Smokers were less likely to have consumed vegetables, fruits (particularly fruits and vegetables high in vitamins C and A), high fiber grains, low fat milk, and vitamin and mineral supplements than non-smokers. A negative linear trend was found between smoking intensity and intake of several categories of fruits and vegetables. These data suggest that the high cancer risk associated with smoking is compounded by somewhat lower intake of nutrients and foods which are thought to be cancer protective. (*Am J Public Health* 1990; 80:1323–1329.)

Introduction

Cigarette smoking is the biggest single health habit that contributes to preventable chronic disease in the United States especially cancer of the lung, larynx, oral cavity, and esophagus as well as coronary artery disease and emphysema.[1] Other cancers, such as bladder, kidney, pancreas, cervix, and stomach are also associated with cigarette consumption. Cigarette use in the US has been estimated to be a causative factor in 30 percent of all cancer deaths and in 87 percent of all lung cancer deaths.[2] It has also been estimated that diet is a causative factor in 35 percent (with a possible range of 10–70 percent) of all cancer deaths. While smoking, food, and alcohol consumption each are lifestyle practices associated with cancer risk, when they occur together some authors assert they act synergistically to produce risks which are greater than the sum of their parts.[3]

Compared to non-smokers, smokers consume more alcohol and coffee, take more risks, have more sexual partners, exercise less, sleep less, take vitamin and mineral supplements less, and skip breakfast more.[4–11] Furthermore, several of these poor health habits are more likely to occur with increasing average number of cigarettes smoked per day.[8]

Among smokers, those with either higher dietary intakes of vitamin and/or carotene or higher serum carotenoids are at reduced risk for lung cancer,[12–25] and several studies have examined the vitamin A, carotenoid, or energy intake differences between smokers and non-smokers.[26–30] A recent study showed an inverse association between intake of vitamin C and smoking.[31] Only one study[32] of 45–59 year old men enrolled in a prospective heart disease trial in Wales, however, examined total nutrient intake differences between smokers and non-smokers, and smokers were found to have lower intakes of most nutrients.

Understanding the dietary patterns of those who smoke compared to those who do not smoke is important for health professionals seeking to assess disease risk and educate individuals regarding healthy lifestyles. We used data from a large nationally representative survey, the Second National Health and Nutrition Examination Survey (NHANES II),[33] conducted from 1976–80, to determine whether smokers significantly differ from non-smokers in both nutrient and food intake.

Methods

NHANES II used a probability sample of the civilian non-institutionalized US population ages 6 months to 74 years. The complex sample design and sample weights are described in detail elsewhere.[34] Mobile examination centers employing trained teams of physicians, nurses, dietitians, and technicians traveled to and collected data from 64 sites throughout the country.

NHANES II 24-hour dietary recall data from 11,260 adults ages 19–74 years were used to assess dietary intake. For these analyses, races other than Black or White were excluded because of small sample sizes. Also excluded were individuals (N = 280) with imputed, surrogate, or unreliable 24-hours recall data. Trained interviewers collected dietary intake data from the day before the interview. Three-dimensional food portion models were used to help individuals accurately report portion sizes.[35] Dietary data were coded by the interviewers within 72 hours of data collection and analyzed for nutrient content using current nutrient values. Nutrient values for folate and dietary fiber, however, were not available on NHANES II tapes and were added later by Subar, *et al*,[36] and Lanza, *et al*,[37] respectively.

A smoking history was obtained from all subjects. Individuals were placed into categories of current, former, and never smokers, and current smokers were divided into categories of light, moderate, and heavy smokers based upon reported average use of 1–14, 15–24, or ≥25 cigarettes/day, respectively. Initial analyses showed few differences in nutrient or food intakes from 24-hour recall data between never and former smokers and therefore they were combined, creating a group of current non-smokers. Individuals who were not cigarette smokers but smoked either pipes (N = 63) or cigars (N = 140) <6/week, and <3/week, respectively, were included as non-smokers because usage was considered too infrequent to warrant exclusion. Frequent pipe or cigar users (N = 398) were excluded from the analyses.

Nutrient intake differences between current smokers and non-smokers, and among current non-smokers and light, moderate, and heavy smokers in the 24-hour recall data set were examined by race, sex, and broad age groups (19–29, 30–54, and 55–74 years). Differences in food intake were determined using food groups developed by Patterson and Block.[38] The food groups created were based upon the

interim dietary guidelines by the National Research Council's report, *Diet, Nutrition and Cancer*,[39] and those of the American Cancer Society.[40] An inclusive "all vegetables" category was developed as well as the following vegetable subcategories: cruciferous vegetables (i.e. broccoli, cauliflower, brussels sprouts, cabbage), deep yellow vegetables (carrots, winter squash, sweet potatoes), fiber-rich vegetables (dried peas, beans, corn), and "garden vegetables" (all vegetables except white potatoes, dried peas and beans, and salad). Fruits and vegetables were also subdivided into categories of those high in either vitamin A (i.e. carrots, spinach, cantaloupe) or vitamin C (i.e. oranges, grapefruit, broccoli). A complete listing of foods in each category has been published.[38] Regardless of portion size or numer of servings, individuals were described as having consumed or not consumed food(s) within each food group based upon 24-hour recall data. Preliminary analyses of food group intake indicated that such coding yielded few differences by sex and, therefore, individuals were categorized by age and race only.

In addition to univariate analyses described above, multivariate analyses of nutrient and food intake were performed adjusting for age, kcal/daily, poverty index ratio or PIR (an income status index which takes into account household income, family size, and the income necessary to maintain a family at the time the study was conducted), and sex. These analyses were performed separately for Whites and Blacks because of the known racial differences in consumption of foods and nutrients.[41]

Separate analyses by sex-race categories were performed to determine whether smoking category based upon average daily cigarette consumption, as measured in half packs of cigarettes consumed, was linearly related to intake of nutrients or food groups. Each nutrient or food group, acting as a dependent variable in the model which adjusted for age, examined the effect of half packs of cigarettes consumed. For purposes of these analyses, quartiles of nutrient intake by race-sex groups were used.

Statistical analyses were performed using SAS[42] with appropriate population weights permitting inferences about the total adult US Black and White population. Standard errors were calculated using SESUDAAN,[43] a program designed to account for the complex survey design. The SURREGR[44] program for complex samples was used in multivariate analysis for the White population, but because of the lack of dispersion of Blacks throughout strata and primary sampling units (PSU), an unweighted regression analysis was used for Blacks. Logistic regressions were performed using the RTIlogt program.[45] This application uses the Taylor expansion series to estimate the variances.

Results

Food Group Intake Differences

Analyses by age, race, sex, and current smoking status showed a larger proportion of Black men (55 percent) smoked during the period of the NHANES II study than in any other sex-race category, followed by White men (43 percent), White women (34 percent), and Black women (34 percent). In all age-race-sex groups, approximately 50 percent of all smokers are 30–54 years of age, while approximately one-third and 15 percent are ages 19–29 and 55–74 years, respectively.

Tables 1 and 2 present univariate analyses of food group intake of smokers and non-smokers by age for Whites and Blacks, respectively. With few exceptions, intake of vegetable categories except "starchy fibrous" is moderately higher among non-smokers as compared to smokers in all age-race groups. Multivariate analyses which adjusted for age, kcal/day, PIR, and sex confirmed these results among Whites. Both univariate and multivariate analyses show that non-smokers of both races have a strikingly higher intake of fruits compared to smokers with percentage differences as high as 19 percent (unadjusted) for 19–29 and 30–54 year old Whites, and 55–74 year old Blacks. For the categories of high fiber grains and fruits or vegetables high in either vitamin C or vitamin A, non-smokers in all age-race categories have a greater intake than smokers, a finding confirmed after multivarate adjustment. For high fiber grains, however, it should be noted that Blacks have much lower intakes than Whites with the highest intakes among Black non-smokers equal to or less than the lowest intakes of White smokers.

a) CI = Confidence interval.
b) Data based upon reported "regular" usage of vitamin/mineral supplements.
*Lower limit truncated to 0.0 from a negative value.

Univariate analyses (Tables 1 and 2) showed that non-smokers compared to smokers tended to consume equal amounts of red meat, but more poultry/fish and skim milk, and less bacon/luncheon meats, and whole milk. These findings were confirmed in the multivariate model. In addition, among Whites and most Blacks, non-smokers were more likely to take vitamin/mineral supplements. Blacks, however, were low supplement users overall.

Nutrient Intake Differences

Tables 3 and 4 present, for Whites and Blacks, respectively, univariate analyses of mean intake data for energy, seven nutrients, dietary fiber, and cholesterol by age, sex, and current smoking status. Analyses were also performed for calcium, iron, thiamin, riboflavin, niacin, oleic acid, and linoleic acid, but results showed few or no differences by smoking status (data available upon request to author). As found in past research of the NHANES II data set,[27] smokers tended to consume more kcal than non-smokers. Few intake differences between smokers and non-smokers were found with respect to fat, protein, carbohydrate, and cholesterol.

Mean vitamin C intake is higher among non-smokers in all age-race-sex categories (Tables 3 and 4) with the difference being most striking among White males. After controlling for age, kcal, PIR, and sex, a negative association remained between smoking and vitamin C consumption for both races.

Univariate analyses of vitamin A intake are inconsistent among age-sex-race categories with non-smokers consuming greater or equal amounts compared to smokers. In multivariate analysis, however, a negative association was found between smoking and vitamin A intake among Whites.

With the exception of older Black males, there is a tendency among all age-race-sex groups for smokers to consume less folate and dietary fiber than non-smokers (Tables 3 and 4). After adjustment, these results were confirmed for dietary fiber in both Blacks and Whites and for folate in Whites only.

Linear Trends in Nutrient and Food Intake

Using multiple linear regression, nutrient intake was examined for a linear relationship between sex-specific quintile of nutrient intake and cigarette consumption, as measured in half packs of cigarettes consumed. No trends were found among Blacks for any food or nutrients after adjusting for age. In Whites, after adjusting for age, negative associations between cigarette consumption and both vitamins C and A were found for males ($\beta = -0.11$ s.e. $= 0.015$, $\beta = -0.06$ s.e. $= 0.012$, respectively) and females ($\beta = -0.14$ s.e. $= 0.014$, $\beta = -0.08$ s.e. $= 0.014$, respectively). Similar negative associations were found for folate among males ($\beta = -0.06$ s.e. $= 0.014$) and females ($\beta = -0.09$ s.e. $= 0.017$) and for dietary fiber among males ($\beta = -0.09$ s.e. $= 0.015$) and females ($\beta = -0.11$ s.e. $= 0.017$). A positive association was found between cigarette consumption and intake of saturated fatty acids for males ($\beta = 0.04$ s.e. $= 0.013$).

For food group intake adjusted for age, a negative linear trend existed between increasing cigarette consumption and intake of any vegetable (males $\beta = -0.10$ s.e. $= 0.028$ and females $\beta = -0.10$ s.e. $= 0.029$), garden vegetables (males $\beta = -0.09$ s.e. $= 0.020$ and females $\beta = -0.10$ s.e. $= 0.027$), any fruit (males $\beta = -0.22$ s.e. $= 0.027$ and females $\beta = -0.34$ s.e. $= 0.030$), fruits or vegetables high in vitamin A (males $\beta = -0.13$ s.e. $= 0.035$ and females $\beta = -0.18$ s.e. $= 0.045$), fruits or vegetables high in vitamin C (males $\beta = -0.21$ s.e. $= 0.031$ and females $\beta = -0.19$ s.e. $= 0.035$), high fiber grains (males $\beta = -0.23$ s.e. $= 0.038$ and females $\beta = -0.15$ s.e. $= 0.048$), low fat milk (males $\beta = -0.17$ s.e. $= 0.025$ and females $\beta = -0.22$ s.e. $= 0.040$), and vitamin and mineral supplements among all Whites. In White males a negative association was found between increasing consumption of cigarettes and salad ($\beta = -0.08$ s.e. $= 0.018$), any cruciferous vegetable ($\beta = -0.09$ s.e. 0.032), and poultry and fish ($\beta = -0.07$ s.e. $= 0.023$).

Discussion

Several limitations of this study should be mentioned. Twenty-four recalls are considered suitable for the study of

group but not individual means.[46] At least one investigator, however, has suggested that the bias due to reporting error inherent in the method may be greater than the difference detected between groups.[47] Given the large size and scope of NHANES II, the 24-hour recall data are likely to be appropriate for the group analysis presented here, but should be viewed with caution because of potential bias. In particular, conclusions regarding nutrients known to have large variability (such as vitamin A) may be subject to question when small groups are examined.[47] Because the number of Blacks sampled in NHANES II is relatively small in comparison to Whites, the results for Blacks cannot be viewed with the same degree of confidence. Finally, the coding of intake of food groups which is based upon mentions from the recalls yields no information regarding portion size and, therefore, is useful but imprecise quantitatively.

Smoking and diet are among the top 10 risk factors thought to cause the majority of disease in the US.[48] Our findings suggest that there are important dietary differences between smokers and non-smokers, all tending toward unhealthy patterns. Surprisingly few differences by current smoking status were found for fat, saturated fat, and cholesterol, dietary variables associated with coronary heart disease. Smokers did, however, consume less poultry/fish and low fat milk and more whole milk and luncheon meats than non-smokers. With respect to cancer prevention, however, there is interest not only in the role of fat, but also in the roles of fruits, vegetables, fiber, vitamin A/carotenoids, vitamin C, and folate. For all these foods or dietary constituents, we found that smokers, in general, consume less than non-smokers, with vitamin C/fruit intake showing the greatest and most consistent difference across all age-sex-race groups.

Our findings with respect to vitamin C and fruits are intriguing for several reasons. First, vitamin C is thought to protect against cancer through reduction functions which serve to both prevent carcinogens from forming and decrease the carcinogenic effects of certain chemical agents and through the enhancement of host resistance.[49] Second, several studies have shown that smokers have lower serum vitamin C levels than non-smokers, and that vitamin C turnover in smokers is higher than in non-smokers.[31,50–52] Several investigators have suggested, therefore, that smokers have increased vitamin C requirements. While mean vitamin C intake data suggest that smokers are meeting their Recommended Dietary Allowance (RDA) for vitamin C (60 mg),[53] this level may not be high enough to counteract the increased vitamin C turnover resulting from their smoking habit. Our data suggest that this very group, which requires more vitamin C, is consuming significantly less. While we do not account for vitamin C intake from supplements, the data show that smokers are less likely to be taking supplements than non-smokers. Third, our vitamin C and fruit results are

*High value due to 3 individuals with unusually large intakes of liver and/or eggs and/or carrots.

consistent with research suggesting that smoking (via nicotine) decreases the desire for sweet foods and in particular, fruit juices.[54,55] While our results may, in part, be explained by taste preference characteristics due to the metabolic effects of nicotine, this does not resolve the differences found between smokers and non-smokers in their intake of other non-sweet foods.

High intakes of dietary fiber are suspected to be a preventive factor in colon cancer,[56] and the National Cancer Institute recommends that individuals consume 20–30 gm of dietary fiber daily.[57] Past research based on NHANES II data shows that intake of dietary fiber in the US is much lower than this recommendation,[37] and we show that smokers have among the lowest intakes. While tobacco use is not known to be related to bowel cancer, our results suggest that smokers could be at higher risk for this cancer through related dietary lifestyle habits. Furthermore, our results indicate that this lower intake results from lower consumption of several key sources[58] of dietary fiber: vegetables, whole grains, and fruits.

Consistent with past research,[30,32] we found that smokers have, for the most part, lower intakes of vitamin A than non-smokers. While smokers have 25 times the risk of developing lung cancer compared to non-smokers, both low dietary intake and serum vitamin A and/or carotenoids have been shown to increase smoking adjusted lung cancer risk in the range of 1.3 to 2.7 times.[13,14,16,19–25] Furthermore, several studies have shown that low dietary or serum vitamin A/carotenoid levels increase lung cancer risk (range: 1.3–8.1) among smokers, including the heaviest and those who have smoked the longest.[12,16,18,20,22,24,25] Evidence of dietary protection is strongest for carotenoids (from plants) versus retinol sources (from animals).[59] A separate measure of the carotenoid or retinol composition of foods was not available in our database, but our finding that smokers consume fewer fruits or vegetables high in vitamin A, and fewer fruits and vegetables overall, suggest that smokers have lower carotenoid intakes than non-smokers. Stryker, *et al*,[28] have suggested that smokers need to increase their intake of carotenoids to achieve blood levels comparable to their non-smoking counterparts. Our results show that smokers, who may gain some protection from lung cancer by high carotenoid intake, are less likely than non-smokers to be consuming carotenoid-dense foods. Furthermore, former smokers, who enjoy gradually declining lung cancer risk, should be encouraged toward improved nutrition in an effort to possibly accelerate the decline.

A few reports have suggested that folate may be protective for both lung and cervical cancer.[60–62] While our results with respect to intake differences between smokers and non-smokers are less striking for folate than for vitamin C, such differences should be noted in that they fit into a general pattern of lower intake of fruits, vegetables and high fiber grains among smokers.

Questions remain as to whether specific dietary factors such as vitamin A, carotenoids, and vitamin C are the operative cancer protective factors in foods or whether some other yet unknown factor(s) is responsible. Studies have shown that intake of cruciferous vegetables, fruits and vegetables, and especially yellow-orange and green vegetables have protective effects not only for lung cancer, but also for breast, colon, prostate, bladder, oral cavity, stomach and cervical cancers.[56] Our results show that intake of all these foods is significantly lower among smokers. This suggests that smokers may be at higher risk for many cancers, some of which are non-smoking-related. Of particular interest is our finding that for several of the cancer protective food groups, there are modest but consistent trends for intake to decrease as cigarette consumption increases. Thus, the more one tends to smoke, the more one increases cancer risk, the less one tends to consume fruits, vegetables, and high fiber grains. These findings are similar to that of Schoenborn and Benson[8] regarding other lifestyle factors such as sleeping less than six hours per night, skipping breakfast, being less physically active, being sedentary, and drinking heavily.

One possible explanation for lower intakes of nutrients and some foods among smokers may be that smokers compared to non-smokers tend to be greater consumers of alcoholic beverages[5] and, therefore, may replace calories and nutrients from food sources with those from drinks. Because we had no data regarding the contribution of alcohol to either the caloric or carbohydrate content of the 24-hour recalls we analyzed, we were not able to explore this possibility, and past research yields conflicting results.[29,63] Further research is necessary to determine whether alcohol consumption plays a significant role in the lower intake of nutrients and foods found among smokers in this research.

Our findings of lower intakes of vitamin A, vitamin C, fiber, and folate among smokers are correlated in that all these nutrients are common to vegetables, fruits, and grains, foods for which we also found lower consumption among smokers. The task of understanding how nutrients and/or foods protect or promote cancer while considering other risk factors such as smoking is difficult. We have shown that smokers, who are known to be at increased risk for several cancers, have lower intake of nutrients and foods associated with cancer prevention than non-smokers. The evidence is clear that smoking is a habit which leads to or is lead by other lifestyle practices, and we have shown that yet another important health habit is associated with smoking: food intake. This suggests that analyses in future epidemiological research regarding cancer prevention or etiology account for the possible confounding of smoking and diet.

Smoking cessation is the single biggest prevention measure for purposes of cancer prevention and control, particularly with respect to lung cancer.[2] Individuals who smoke are clearly at greatly increased risk from their tobacco use. However, this study suggests that they may be at some slightly additional risk from dietary intake low in critical nutrients. While more research is needed regarding smoking and diet, smokers and ex-smokers may be well advised to increase their intake of fruits, vegetables, and high fiber grains. In the meantime, physicians and the public should be aware that some smokers have low intakes of foods or nutrients associated with decreased cancer risk.

Depressive Mood, the Single-Parent Home, and Adolescent Cigarette Smoking

LIRIO S. COVEY, PHD, AND DEBBIE TAM

Abstract: The association between depressive mood and cigarette smoking among adolescents was examined within a multivariate model. Subjects were 205 eleventh graders (123 boys and 82 girls) enrolled in a Northeast metropolitan public high school for science-oriented students. Logistic regression analysis showed an independent relation of depressive mood, friends' smoking behavior, and living in a single-parent home with cigarette smoking. Depression scores correlated with the number of cigarettes smoked. These associations suggest that depressive mood and stress may contribute to the onset of smoking. (*Am J Public Health* 1990; 80:1330–1333.)

Introduction

A host of factors have been investigated in numerous attempts to determine the antecedents of cigarette smoking among adolescents. Peer and family smoking behavior have been consistently implicated[1-3]; while less evidence has been demonstrated for the effects of psychological traits, knowledge and attitudes about smoking, school achievement, and demographic characteristics.[1]

A prospective study involving 1,004 subjects found that depressive symptoms reported at ages 15–16 predicted the frequency and duration of cigarette smoking nine years later.[4] This association was not seen for future alcohol or drug use. Another study found higher scores on the Beck Depression Inventory among cigarette smokers than in nonsmokers in males.[5] Both studies limited analysis to simple associations; neither controlled for the effect of other known risk factors. We have found no other attempts to examine the relation between depression and smoking among adolescents. In contrast, a recent paper cited seven studies that examined the relation between depressive disorders and drug and alcohol abuse.[6]

The present study reports our investigation into the relation between depressive symptoms and cigarette smoking among adolescents within the context of a multifactorial model.

Methods

Subjects were 205 11th graders (123 boys and 82 girls) enrolled in a public science high school in a Northeast metropolitan area. This sample included all subjects present on the day our questionnaire was administered in seven non-elective health education classes; they comprised 35 percent of the school's total 11th grade population in the school year 1987–88. Enrollment into this school is competitive and requires passing a qualifying examination. We did not obtain ethnic information from our subjects. School records, however, showed the following ethnic breakdown for the total 11th grade class: 45 percent White, 33 percent Asian, 14 percent Black, 8 percent Hispanic, 0.5 percent American Indian. It is unlikely that our sample deviated markedly from the total 11th grade class in ethnic distribution.

To enhance compliance and candid reporting, we developed a questionnaire that was short (limited to a single, double-sided page), anonymous, and noninclusive of potentially sensitive areas (e.g. grade point average, ethnicity, use of alcohol or drugs). Certain items were not answered by some respondents, accounting for the uneven group totals shown in the accompanying tables.

Subjects were asked whether or not they were regular smokers (at least one cigarette a day), the amount they smoked, the age of smoking onset, and the brand of cigarettes most frequently smoked. We also asked about the smoking behavior of parents, siblings, and friends; estimated parents' annual income; and number of siblings.

We selected 15 of the 20 (CES-D) items[7] to measure level of depressive symptomatology. The feasibility of using this scale with adolescents[8] and that of using a shortened version[9] have been demonstrated. To determine the specificity of an effect of depression, we included two other mental health measures: seven items from an inventory of "worries" used with schoolchildren[10] and from other instruments, assembled seven items assessing level of satisfaction with various life concerns (Appendix). Internal reliability (Cronbach) coefficients based on the total sample were 0.81 for the depression scale, 0.74 for worry, and 0.73 for satisfaction items.

We measured family structure by asking if the subject lived with one or both parents but did not determine whether the custodial parent was separated, divorced or widowed.

Yates corrected chi square analyses and t-tests were used in comparisons of boys vs girls, smokers vs nonsmokers, and highly exposed vs less exposed smokers. Multiple logistic regression[11] using a model that included all the study variables was employed to test the independence of observed associations with cigarette smoking. Quantitative measures were dichotomized at their median values.

Results

We found an overall similarity between boys and girls on most of the psychosocial and smoking variables we studied (Table 1). The mean age of the sample was 16.1 (s.d. = 1.7) years. They were predominantly middle class (about 50 percent estimated their family income to be \$25,000–\$50,000), and living in two-parent households (73.6 percent). Only two children were not living with either parent.

The group prevalence of regular smoking (at least one cigarette daily) was 26.8 percent. It was higher in boys, who also reported smoking more cigarettes, than in girls. Girls reported a lower smoking rate among their mothers than their fathers, a difference that was not seen among the boys (Table 1).

Not the only child	96 (78.0)	63 (76.8)	159 (77.6)
Living with both parents	93 (76.2)	57 (69.5)	150 (73.6)
Regular smokers	34 (27.6)	21 (25.6)	55 (26.8)
Frequency of smoking			
1 cigarette/day	14 (41.2)	12 (60.0)	26 (48.1)
About 10–20	10 (29.4)	6 (30.0)	16 (29.6)
More than 20	10 (29.4)	2 (10.0)	12 (22.2)
Began smoking <15 yrs	19 (55.9)	12 (57.1)	31 (56.3)
Mean age began (s.d.)	14.1 (1.4)	15.5 (6.1)	14.7 (4.0)
Smoke brand with ≥1 mg nicotine	26 (76.5)	10 (52.4)	36 (66.3)
Friends who smoke			
Most or All	23 (22.1)	13 (17.6)	36 (20.3)
Some	49 (47.1)	34 (45.9)	83 (46.6)
None	32 (30.9)	27 (36.5)	59 (33.1)
Mother smokes:	26 (27.1)	9 (11.1)	35 (20.7)
Father smokes:	25 (26.6)	21 (25.9)	46 (27.5)
Siblings smoke:	7 (8.4)	8 (9.9)	15 (10.8)

Note: Percents shown are based on group totals that do not include missing answers.

Mean scores for each of the three mental health variables, i.e. depression, worry, and satisfaction, did not differ by sex. Depression was positively correlated with worry, $r = .30$, (205) $p < .001$ and negatively correlated with satisfaction, $r = -.36$, (205) $p < .001$. Satisfaction and worry scores were negatively correlated, $r = -.16$, (205) $p < .02$.

Rates of cigarette smoking by selected factors are shown in Table 2. The most striking association with cigarette smoking was observed for peer smoking behavior. Smokers were also more depressed and worried, and less satisfied, than were nonsmokers (Table 3).

TABLE 2—Prevalence of Regular Smoking by Selected Characteristics in a Sample of 205 11th Graders

Characteristics	% Smokers	Total N
Age		
≤16 years	23.7	142
>16 years	37.7	61
Family income		
<$25,000	28.0	25
$25,000–$49,999	28.2	85
$50,000>	28.3	60
Only child

No	27.6	123
Friends smoke		
All	100.0	6
Most	80.0	30
Some	24.1	83
None	8.5	59

Note: Missing answers account for uneven group totals.

Multiple regression analysis (Table 4) showed that three variables were independently related with smoking status. As in the univariate analyses, the strongest relationship was observed for friends' smoking behavior (odds ratio = 7.7). An excess risk for smoking was also seen for respondents who scored above the group median (11>) on the shortened CES-D scale (odds ratio = 3.9), and for those who lived in a single-parent home (odds ratio = 1.9). Only children showed some risk for being a smoker but the confidence interval of the odds ratio (1.6) included 1. No interaction term was associated with smoking.

Smokers who smoked a pack or more a day reported a depression score of 22.7 compared to 15.4 for smokers of fewer cigarettes (difference = 7.3; 95% CL = 2.5, 12.1). No relation between age began smoking or nicotine yield of brand smoked and depressive symptoms was observed.

Discussion

Our sample was drawn from a metropolitan high school for talented, high-achieving students. We can only speculate about the extent to which the competitive and demanding climate of their school environment engendered the preva-

lence of depressive symptoms in our sample or the higher rate of smoking we observed (27 percent) compared to the rate seen in similar aged national samples (18 percent).[12] While these special characteristics of our subjects may limit the generalizability of our findings, they do not reduce their validity.

The strong and independent relationship between depressive symptoms and cigarette smoking confirms previous results obtained prospectively[4] and in a cross-sectional design.[8] The correlational nature of our study does not permit us to infer a causal relation or the direction of a causal sequence involving cigarettes and depression. However, neither a direct nor indirect effect from cigarette smoking to depression is likely. There is no evidence that nicotine, the major pharmacological agent in tobacco, causes depression,[13] and our data did not show more depression among smokers of high nicotine-content tobacco. Also, we did not observe that having more friends who smoked (which may reflect membership in a minority, deviant group) is correlated with higher depression. On the other hand, Kandel's observation[4] based on longitudinal data that cigarette smoking in adulthood is a sequela of depressive symptoms in adolescence supports an antecedent, if not causal, relation of depressive affect with cigarette smoking. An association between clinical depression and smoking status has been found in adult samples.[14,15] It remains to be seen whether such an association exists among adolescents as well since the CES-D, while potentially useful as a screening instrument, does not diagnose clinical depression.[16]

The rate of smoking among subjects living in single-parent homes was higher than the smoking rate in other subjects (37 vs 22 percent, respectively), an association that was independent of peer smoking behavior or depression rating. This finding agrees with an earlier observation that disruptive family events are directly associated with adolescent cigarette smoking.[17] In accord with Wills'[18] coping model of smoking in adolescence, cigarette smoking may be an attempt to mitigate the stresses brought on by parents' marital break-up. This explanation is compatible with the notion that parents' divorce may exacerbate the trend towards maladaptive coping among adolescents.[19] We offer these speculations with caution, however, since we obtained only limited information regarding the circumstances surrounding parents' separation.

Our results suggest that merely teaching youngsters how to "just say no" to their peers may not be enough. Depressive mood and parental separation appear to be additional risk factors contributing to the prevalence of smoking among adolescents. Multicomponent prevention approaches that will also address adolescents' emotional needs and the strains engendered by the home situation are indicated.

APPENDIX

Depression Items (15 from the CES-D Scale)

Below is a list of the ways you might have felt or behaved. Please indicate your answer.

a) Rarely or none of the time (less than 1 day)
b) Some or a little of the time (1–2 days)
c) Occasionally or a moderate amount of time (3–4 days)
d) Most or all of the time (5–7 days)

During the past week:

A. I was bothered by things that usually don't bother me
B. I did not feel like eating; my appetite was poor.
C. I felt that I could not shake off the blues.
D. I felt that I was just as good as other people.
E. I felt depressed.
F. I felt hopeful about the future.
G. I thought my life had been a failure.
H. My sleep was restless.
I. I was happy.
J. I talked less than usual.
K. I felt lonely.
L. People were unfriendly.
M. I had crying spells.
N. I felt that people dislike me.
O. I could not get "going".

Worry Items

Almost everyone at one time or another is worried about something. Different people worry about different things. Read and check appropriately if it worries you.

	A lot	A little	Hardly ever
1. Not getting along with your parents	—	—	—
2. Not being popular	—	—	—
3. Feeling left out of things	—	—	—
4. Being made fun of	—	—	—
5. Being looked down upon	—	—	—

Satisfaction Items

For each area of life, choose the letter that corresponds with the level of satisfaction you get from that area.

A) a very great deal
B) a great deal
C) quite a lot
D) a fair amount
E) a little
F) none

a) city or place you live in ___
b) school work ___
c) hobbies or sports activities ___
d) extracurricular activities ___
e) family life ___
f) your friendships ___
g) your physical condition ___

Effects of Individually Motivating Smoking Cessation in Male Blue Collar Workers

Kaye H. Kilburn, MD, and Raphael H. Warshaw, BA

Abstract: Adverse demonstrable health effects linked to the individual's smoking were shown to 2,689 American workers to motivate cessation during routine examinations to detect asbestosis. This intervention was evaluated six to 25 months later by a mailed questionnaire and by telephone to non-responders. Results were compared to yearly quit rates of 2.5 percent to 5 percent for 736 workers who were ex-smokers at the initial examination. Of the 504 men who responded by mail, 29.8 percent had quit smoking, 35.9 percent had cut down from a mean of 28 to 13 cigarettes per day, and 34.3 percent were smoking as before. Subsequent follow-up at one year showed that 25.6 percent remained quit, and that 23 percent of those who cut down had quit, for an overall quit rate of 34 percent. Of 101 non-responders contacted by telephone, 17 percent had quit and 53 percent had reduced smoking. In both samples, those who quit were more likely to have had lower alveolar carbon monoxide (CO$_a$) levels, to be older, and to have had asbestosis. Responders by mail were the same age as non-responders but had smoked longer, had higher prevalences of asbestosis, emphysema, chronic bronchitis and higher CO$_a$. Demonstration of the adverse personal effects of smoking appear to have contributed to the quit rates or reduced smoking rates in 65 percent of the responding workers. (*Am J Public Health* 1990; 80:1334–1337.)

Introduction

Smoking cigarettes is the largest preventable cause of illness and premature death in the United States. It is responsible for 30 percent of all cancer deaths.[1] Asbestos is the single most important occupational cause of lung cancer.[2] Occupational asbestos exposure raises the lung cancer risk five times and combined with cigarette smoking increases the risks 50- to 100-fold.[3] Smoking and asbestos are synergistic in producing pulmonary fibrosis and functional impairment as well.[4] Despite the fact that blue collar workers in trades exposed to asbestos usually smoke more than others in the work force,[4] few efforts have been aimed at modifying their smoking.[5] In one reported exception, 65 percent of smokers in a California shipyard had quit smoking, leaving only 18 percent of current workers still smoking.[6] This was attributed to their being made aware of their own health risks of smoking combined with asbestos exposure. Thus, we wondered whether other asbestos exposed workers could be motivated to quit smoking if a physician and other health workers pointed out the adverse effects of smoking on their own body and bodily functions. We compared the effects of this intervention to the yearly quit smoking rates in workers who were ex-smokers at the time of study.

Methods

The men studied had been exposed to asbestos in construction trades and shipbuilding as active or retired members of the International Brotherhood of Boilermakers, Iron Ship Builders, Blacksmiths and Forgers, the United Association of Plumbers and Pipefitters or other unions. All men were White . They had to have been exposed to asbestos at least 15 years earlier and for a duration of at least five years. Ages ranged from mid-thirties to mid-eighties. We screened 4,183 of these men from 20 locations in the United States, from Oregon and Southern California to Florida and North Dakota. There were 19.6 percent who had never smoked, 17.6 percent were ex-smokers, and 62.8 percent were current smokers. The intervention target was 2,627 current smokers who received our follow-up letter. The comparison populations for smoking cessation rates were 134 men who had quit in the preceding year and 736 men classified as ex-smokers by interview backed by alveolar carbon monoxide levels.

All men had completed questionnaires in their union halls concerning respiratory symptoms, onset, intensity and duration of cigarette smoking, occupational exposures and exercise tolerance. They had been given a brief physical examination including measurement of height, weight, pulse rate, blood pressure, auscultation of the chest and presence of clubbing, cyanosis, and edema. Chronic bronchitis was diagnosed from the criteria of cough and sputum production for more than three months of two consecutive years.

Smoking status reported on questionnaire, was verified by measuring the level of carbon monoxide in alveolar gas (CO$_a$) during 20 seconds of breath holding with a fuel cell.[4] Vital capacity, forced expiratory volume in one second and flow rates,[7] were measured by spirometry. Each worker's measurements were expressed as percentage of predicted obtained by regression equations.[8] Total lung capacity was measured by planimetering of posteroanterior and lateral chest x-rays, obtained at full inflation of the lungs for area and volumes calculated.[9]

To motivate quitting, the effects of cigarette smoking including symptoms (particularly cough and sputum), chest x-ray changes, abnormal pulmonary function tests and findings on physical examination were explained by the team of examiners. The physician made clear the contribution of cigarette smoking when signs of asbestosis were found in the lung or pleura on the worker's x-ray[10] and when signs of emphysema, such as hyperlucent lung fields, hyperinflation, bullae and other abnormalities[11] were present. He also related these findings to shortness of breath and limited endurance in climbing hills and stairs and observed that these symptoms and abnormalities would progress if the worker continued to smoke but would stop progressing if he stopped smoking. The extremely high risk of dying of lung cancer in asbestos-exposed workers who smoke was also emphasized. Elevated alveolar carbon monoxide (CO$_a$) levels and reduced spirometric flow curves were linked to smoking as were current or eventual shortness of breath by senior technicians.

Address reprint requests to Kaye H. Kilburn, MD, Ralph Edgington Professor of Medicine, School of Medicine, University of Southern California, 2025 Zonal Avenue, HMR 913, Los Angeles, CA 90033. Mr. Warxhaw is a Research Associate at USC. Dr. Kilburn is also affiliated with Workers Disease Detection Services of San Dimas, CA. This paper, submitted to the Journal May 1, 1989, was revised and accepted for publication March 29, 1990.

During the physical examination a nurse practitioner pointed out to those with diminished breath sounds and wheezes that these were characteristic effects of smoking, which indicated obstruction to airflow which in turn causes shortness of breath. Finally, while assisting workers with occupational, medical and pulmonary histories, interviewers emphasized adverse health effects of smoking including the risks for cancer and impairment of breathing which are enhanced by asbestos exposure.

After data were assembled, a personal letter summarizing the findings was sent to each worker from the physician which enclosed results of his pulmonary function tests with the abnormalities identified. Each letter emphasized the greatly increased risk of lung cancer for asbestos-exposed workers who smoke cigarettes.

From six to 25 months after the asbestos screening and study, a letter was sent to each man who was a current smoker. A brief questionnaire was enclosed querying the worker's recall of the screening and report letter, and his current smoking status (quit, cut down, or continued at the same level). He was asked to report the current number of cigarettes smoked per day and whether he still desired to quit. Decreased smoking was defined by the number of cigarettes per day on re-survey being less than the number reported at the examination.

Letters and questionnaires were mailed to 2,689 current smokers; 50 were returned as not reaching the subject and 12 men responded that they had already quit smoking at the time of the screening, which reduced the base numbers to 2,627.

In the early evening, interviewers questioned by telephone 101 of the non-responders selected at random from the 15 largest study sites across the country. Eleven workers who were not reached by calls placed three times on different evenings were replaced. Interviewers asked the same questions as those in the mailed questionnai[illegible] 101 men recalled the asbestos disease screening [illegible] their being strongly advised to quit smoking. Their responses are compared separately from mail responders.

Fifty of the mail responders selected at random from the 150 who reported quitting and 61 selected at random from the 181 who reported cutting down were asked the same questions in a telephone interview 12 months after the return of the questionnaire. Interviewers did not mention the previous mail questionnaire but, if asked, replied that they were doing an interval follow-up. Data from the mail and telephone questionnaires were merged with the data from the asbestosis and lung disease study[4] and tables were constructed showing means and standard deviations. Stepwise linear regressions were made and a correlation matrix was examined.

Results

The data are based on 504 returned questionnaires, a response rate of 19.2 percent to the mailing, and on the 101 non-responders interviewed by telephone. The mail responders were more likely than the 2,123 non-responders to have smoked longer and to have had asbestosis, emphysema, chronic bronchitis and an elevated CO_a level (Table 1), but were otherwise generally similar to responders. Lapse of time since the original study (six to 25 months) was not associated with differences in response rates or in smoking behavior. The 101 non-responders interviewed by telephone were similar to the mail responders in age (mean of 52 years), mean CO_a (34.8 ppm), and prevalence of asbestosis (33.6 percent), emphysema (15.1 percent), and chronic bronchitis (35.9 percent).

Significant differences compared to "did not respond" are underlined.

Because we lacked a comparison group, we used as historical controls the reported yearly quit rates for the 736 ex-smokers who had been studied for asbestosis and lung diseases at the same time and under identical circumstances to the cigarette smokers and 134 men who quit smoking during the year preceding the study. These were considered to provide the natural smoking attrition rates, before our intervention. The quit rate reported for the year prior to intervention was 4.7 percent and rates varied from 2.5 percent to 5.5 percent, going back 20 years, to 1969.

Of the mail responders, 29.8 percent (150 of 504) had quit smoking after the intervention or after receiving the letter reminding them of their health status (Table 2). Another 8 (1.6 percent) had quit but resumed by the time of inquiry and thus are recidivist smokers. In addition, 35.9 percent reported they had cut down smoking from a mean of 28 to 13 cigarettes per day. The remaining 32.7 percent reported smoking as before but over 90 percent of them said they were still trying to quit. Thus 65.7 percent of the workers who responded by mail had ceased or reduced smoking after the screening and intervention. In the interval telephone follow-up a year after receipt of the questionnaire, the 50 men who had been classified as quitters by mail said they had quit at that time and 43 (86 percent) had remained off cigarettes; seven (14 percent) were recidivists. If these proportions are applied to the whole group, the 25.6 percent of the mail response quitters were not smoking one year after responding to the mail questionnaire. The one-year telephone interview follow-up of 61 men who indicated in the mail questionnaire they had reduced smoking showed that an additional 14 (23 percent) had quit between inquiries and had remained off cigarettes. Applying these quit rates to the entire 504 responders would

TABLE 2—Comparison of Cigarette Smoking, Occupational Exposure, Pulmonary Diagnoses and Pulmonary Function Status of 504 Responders by Mail by Cigarette Smoking Status

predict that 171 (34 percent) had quit at 18 to 37 months after the intervention. Those who continued to smoke averaged 15.8 cigarettes per day, practically identical to the 15.4 percent reported when contacted by mail 12 months earlier.

Among the mail responders, men who had quit or reduced their smoking were older than those who continued smoking, and had smoked somewhat fewer cigarettes but had smoked longer than those who continued smoking. Initial CO_a levels were significantly lower in quitters than in those whose smoking was decreased or unchanged. Prevalence of asbestosis was over twice as high in those who quit or cut down as compared to those who continued. The lowest mean pulmonary function values and the most pack years of smoking were in men who decreased their smoking but had not quit; they also had more airways obstruction, more air trapping, and lower vital capacities.

The telephone interviews of 101 non-responders showed that 17 percent had quit and remained non-smokers, another 2 percent were recidivists, 53 percent had reduced cigarettes smoked per day, and 28 percent continued smoking as before (Table 3). In the telephone sample, fewer had quit but more had reduced their smoking when compared to the mail sample; of the 34 men with asbestosis, 12 (35 percent) had quit and 17 (50 percent) had reduced their smoking.

Discussion

Quit rates of 17 percent by telephone interviews of non-responders and 30 percent by mail questionnaire were 3.6 to 6.4 times the quit rate of 4.7 percent in the previous year and much above the 2.5 percent to 5.5 percent in the preceding 20 years. Thus, for this blue collar population, the demonstration of their examination, lung function, and x-ray findings and personal advice about present or future health problems from smoking appear to have motivated many of them to quit or reduce their smoking.

The difference in quit rates between the men who responded by mail (30 percent) and non-responders contacted by telephone (17 percent) was not surprising. A 19 percent response is not unreasonable considering the interval of 6–25 months after previous contact. Those with a more socially acceptable outcome, i.e. quitting, would be expected to reply more frequently. Nevertheless, if one applies the 17 percent quit rates of those reached by telephone to the entire

mail non-responder group and adds the 171 who quit in the mail responder groups, 531 men are estimated to have quit. This is 20 percent of the 2,627 men screened, at least twice the quit rate of the previous year even if the annual quit rate of 4.7 percent is doubled to make the time intervals comparable.

If decreasing smoking indicates progress toward quitting, then a major proportion (36 percent to 53 percent) of the men were influenced by the intervention. This is supported by the finding in the telephone follow-up that 23 percent of those who had earlier decreased their smoking, quit 12 months later.

Reliability of self reporting has been a controversial subject. Some investigators,[12] have found 95 percent accuracy for telephone interviews compared to personal interviews except for short-term quitters. This reservation would not apply to the long-term quitter. Furthermore, it should be realized that these men did not receive strong or continuous external pressure to quit. They were not even aware, until follow-up, that the intervention was being evaluated. The high correlation between smoking histories and CO_a in the initial study suggested that misleading self-reports about smoking were infrequent.

It is unlikely that the clear differences between quit rates of less than 5.5 percent per year prior to intervention and the 17 percent to 30 percent of new quitters could be due to bias introduced by either the mailed questionnaire or the telephone inquiry. Follow-ups by telephone to those who had responded by mail confirmed their quitting. Veracity was further strengthened by a reported 3.6 percent recidivist rate.

Our intervention was less intense than that in a group of British civil servants who, in hospital because of symptoms or signs of coronary disease or chronic bronchitis or both and received individual advice, were challenged to "consider their situation" and given support and encouragement during four further visits over a period of 12 months. That study had 63 percent of responders (84 percent of the group) who reported being off cigarettes after one year. The present project was also less intensive than a Mayo clinic study of motivated volunteers, mostly referred by physicians in 1975 and seen annually through 1984. They received eight weekly one-hour sessions including presentations from an ear, nose and throat specialist and from a pulmonary physician and achieved a 22.3 percent quit rate at one year,[14] results similar to ours. Nevertheless, our quit rate of 17 to 30 percent of the current smokers plus 36 percent who decreased by 15 cigarettes per day was a substantial beginning.

The men we studied had not volunteered for smoking cessation but were recruited through their unions because of asbestos exposure. Thus, their concerns were whether they had asbestosis, pleural changes, or pulmonary disease. The objective of our intervention was to motivate them to quit smoking, not to help self-motivated volunteers to quit. It appeared to us that the most important motivating factor was measurement of CO_a. Although CO_a had been used previously as a reliability check on smoking histories,[12] in our study it quickly showed these workers a smoking "effect." The smokers' carbon monoxide level was a "big number," in parts per million, compared to that of a nonsmoker or ex-smoker. After CO_a, the two next most powerful motivators seemed to be the x-ray appearance of asbestosis and airways obstruction on the spirogram. Because each individual was "targeted" with personal information, it was a novel experience with strong impact.

Epidemiologic Differences between Chlamydia and Gonorrhea

Helen L. Zimmerman, BA, John J. Potterat, BA, Richard L. Dukes, PhD, John B. Muth, MD, MPH,
Helen P. Zimmerman, BS, RN, James S. Fogle, and Christopher I. Pratts, BA

Abstract: To assess the prevalence, demographics, and transmission patterns of genital chlamydia infection, we screened 3,078 patients, and compared identified cases (N = 511) to gonorrhea cases (N = 291) diagnosed in the same setting. Chlamydia cases were younger and more likely to be White than their gonorrhea counterparts. Chlamydia cases were distributed diffusely; geographic overlap between the two diseases was only about 40 percent. Gonoccocal coinfection was noted in <10 percent of patients with chlamydia. Nearly half of men with chlamydia and four-fifths of women were asymptomatic and most cases were identified through screening or contact tracing. Populations at high risk for chlamydia are seemingly different from those for gonorrhea. Differences may be due to control interventions (active for gonorrhea, passive for chlamydia). Chlamydia case reporting and control initiatives are recommended. (*Am J Public Health* 1990; 80:1338–1342.)

Introduction

Chlamydia trachomatis causes an estimated three to four million infections annually in the United States; its morbidity, particularly salpingitis, is substantial.[1,2] Nevertheless, only about half of the states require its notification to public health officers.[3] Although much has been learned about its etiology and clinical aspects in the last two decades, little has been published about its epidemiology. Until recently, reliable and inexpensive screening tests have not been available.

To develop a sense of chlamydia prevalence, patient characteristics, and transmission patterns, we implemented a year-long investigation during 1988. Unlike gonorrhea, chlamydia is not a reportable disease in Colorado. Thus we present epidemiologic and case-finding observations on cases of genital chlamydia infection that were detected in the public medical sector, and we contrast some of these findings with gonorrhea cases ascertained in the same setting. In addition, we were able to obtain comparative data from a local military post, where chlamydia and gonorrhea surveillance information is routinely collected.

Methods

Demographics

The study site is Colorado Springs, a standard metropolitan area (SMA) with a population of about 400,000 (1988 estimate), 65 miles south of Denver. Ethnically, the population is 83.5 percent White, 6 percent Black, 8.2 percent Hispanic, and 2.3 percent other races; it is about two years younger than the national median of 31.8 years (1986 estimate), principally because of the large military population. The military post hosts 60 percent of the 35,000 active duty military personnel in the SMA, 92 percent of whom are men. The post population is 65 percent White, 27 percent Black, 4 percent Hispanic, and 4 percent other races. The public clinics are in the SMA's only health department.

Case Definition

The definitive diagnosis of genital chlamydia infection is based on performance of a moderately difficult and expensive cell culture isolation technique. Because this technique was beyond our means, identification of cases and testing of their sexual partners in both the public and military sectors was done with a less reliable but affordable test (MicroTrak, Syva Laboratories, Palo Alto). Hence all cases in our study are presumptively diagnosed.

MicroTrak is a direct immunofluorescence assay using monoclonal antibodies that react with all 15 known human chlamydia serovars; it was performed according to the manufacturer's instructions. Three test outcomes are possible: positive, suspicious (the presence of fewer than 10 chlamydial elementary bodies), and negative.

Test Sensitivity

Because the performance characteristics of MicroTrak were not evaluated by the "gold standard" (McCoy cell culture) in our clinical settings, test outcomes may differ from published reports; these usually claim that the sensitivity of a single genital attempt to isolate *Chlamydia trachomatis* by the McCoy cell culture is about 90 percent for men and between 70 percent and 80 percent for women,[4] and MicroTrak's sensitivity compared to cell culture is about 70 percent for men and 90 percent for women, with a specificity of about 98 percent.[5] Therefore, MicroTrak's ability to detect genital chlamydia in men approaches two-thirds, a value almost identical to the one for women. We use two-thirds as a proportion to estimate the shortfall in our case-finding outcomes.

Patient Selection

Clients presenting for genital examination at our health department STD, prenatal, or family planning clinics were screened for chlamydia during calendar year 1988. Gonorrhea screening in these clinics is universal, except in the family planning clinic, where the gonorrhea culture is used for diagnosis or clinical suspicion and results in about 17 percent of clients being tested. Budget constraints permitted chlamydia screening of only half of the clients in the STD clinic: 52.5 percent of 1,546 women and 55.6 percent of 1,657 men. Although STD clinicians were encouraged to screen younger women (under age 25), all sexual partners of patients with genitourinary conditions and all patients with recurring genitourinary symptoms, the clinicians were not bound by

these recommendations. All clients in prenatal (573) and all initial visitors to family planning clinic (772) were screened.

Case-finding

Symptomatic men were asked to identify all sexual partners in the interval from one month before the appearance of their urethral symptoms to the date of their treatment; asymptomatic men and all women were queried about their partners in the 120 days prior to the date of their positive test. In the event that there was only one sexual partner in that interval, these latter patients were asked to identify at least one more sexual partner during the year before their diagnosis. The sexual partners (contacts) were actively sought by encouraging self-referral and through field follow-up. All traced contacts were offered epidemiologic treatment as recommended by the Centers for Disease Control (CDC).[6]

Geographic Distribution

The concentration of cases was mapped; census tracts containing approximately 50 percent of cases were considered Core, those containing the next 30 percent, Adjacent, and the remainder, Peripheral, according to Rothenberg's method.[7]

Data Management

Information was recorded on medical charts, case interview records (CDC form 9.97), and contact investigation reports (CDC form 9.2936). The data were coded and entered, without personal identifiers, onto a VAX 8600 computer (Digital Equipment Co.), and they were analyzed using a standard statistical package (SPSS-X, version 3.1).

Results

Population Selection

Younger clients in STD clinic were likely to be tested for chlamydia; the mean age of those tested was 25.3 years (95% CI = 25.0, 25.6) compared to 26.7 years (95% CI = 26.3, 27.1) for untested clients. No tendency to preferentially test by gender or ethnicity was noted.

There were no demographic or case-finding differences between positive and suspicious cases of chlamydia in men; all are included in this report as probable cases. Clinically, 62 percent of the 45 suspicious cases in men were asymptomatic or minimally symptomatic; 19 presented as sexual partners of known cases and 11 had their infection detected as a consequence of screening. The corresponding percentages in the 198 positive cases were: 41.9 (N = 83), 31.3 (N = 62), and 6.6 (N = 13). Concomitant gonococcal infection was observed in 8.6 percent of the positive cases, but in none of the suspicious cases.

Positive and suspicious chlamydia cases in women differed with respect to age, reason for presentation, and case-finding outcomes. Suspicious cases (N = 38) were more likely to be older, with a mean of 25.5 years (95% CI = 23.5, 27.5) versus a mean of 20.7 for positive cases (95% CI = 20.2, 21.2); to present as a result of perceived genitourinary symptoms (39.5 vs 19.8 percent) rather than as contacts or as screenees, and to have fewer chlamydia infected partners in their sexual environments (19.2 percent vs 35.5); 19.2 percent is close to the background level of chlamydia infection in the sexual partners of women who present in our public clinics. Therefore, suspicious cases in women were deemed possible, rather than probable, cases and excluded from the analysis.

Our final study population consists of the 511 cases of chlamydia classified as probable cases in 1988. There were 243 cases in men (198 positive and 45 suspicious cases), all from the STD clinic, and 268 cases in women: 132 from the STD, 75 from prenatal, and 61 from family planning, clinics.

Age Distribution

Sixty percent of the 243 chlamydia cases in men (mean age = 24.2; 95% CI = 23.5, 25.0) and 84 percent of the 268 cases in women (mean age = 20.7; 95% CI = 20.2, 21.2) are under age 25. Fully half of the women are teenagers, as are 20.7 percent of the men. In contrast, 47.5 percent of the 139 gonorrhea cases in men (mean age = 26.1; 95% CI = 24.8, 27.4) and 70.4 percent of the 152 gonorrhea cases in women are under age 25 (mean = 22.9; 95% CI = 21.9, 23.9). Fifty-six percent of men with gonorrhea are in their twenties, whereas 53.2 percent of women are between ages 17 and 22.

Similar differences are noted for the military cases: 80 percent of the 238 chlamydia cases in men whose age was available (vs 72.4 percent of the 337 gonorrhea cases) and 81.7 percent of the 181 age-available cases in women (vs 68.1 percent of the 91 gonorrhea cases) are under 25 vs over 25 years old. The younger distribution in military cases probably reflects the younger age of such populations. The age distribution, by gender, of the sexual partners of our chlamydia patients was similar to that in cases.

Ethnic Distribution

Representation by Whites is higher in chlamydia than in gonorrhea cases for both men and women (Table 1). A similar pattern is noted for military cases, even though the aggregate venereal burden is overwhelmingly Black (Table 2). The race

*Data not available for 20 cases.

**Data not available for 15 cases.

distribution, by gender, of the sexual partners to our chlamydia patients was similar to that of cases.

Geographic Concentration

In the Colorado Springs SMA, the observed chlamydia cases are more diffusely distributed than gonorrhea cases, and the overall extent of geographic overlap between the two diseases is approximately 40 percent. These differences are mapped in Figures 1 and 2. Whereas 50.5 percent of our overall chlamydia cases are observed in 11 Core census tracts (16.2 percent of the SMA's 68 census tracts), nine (11.8 percent) census tracts comprise the gonorrhea Core (49 percent of cases). Only six of the 14 combined chlamydia and gonorrhea Core census tracts (42.9 percent) overlapped. The Adjacent distribution of chlamydia was more diffuse: 29 percent of chlamydia cases occupied 20 census tracts, versus 29.3 percent of gonorrhea cases which occupied 14 census tracts. Overlap occurred in only nine (36 percent) of the 25 combined chlamydia and gonorrhea Adjacent tracts.

The geographic distribution of the sexual partners of chlamydia patients was similar, except that fully 10 percent of contacts emanated from a single military census tract (where *cases* were not enrolled for this study). Exactly two-thirds of all sexual partners resided in Core/Adjacent census tracts, as opposed to about 80 percent of cases. However, the geographic distribution of infected contacts mirrored that of cases: 47.6 percent resided in the Core, and 37.8 percent in the Adjacent, census tracts.

Clinical Findings

One-half (57 percent) of the chlamydia cases in men presented because of symptoms (54 percent had frank urethritis). The remainder were identified through contact tracing (33 percent) or screening (10 percent); these men were essentially asymptomatic.

Chlamydia cases in women were identified through contact-tracing (20.5 percent) or through screening (59.7 percent); only about one-fifth presented spontaneously for examination.

Of the 2,437 public clinic clients tested simultaneously for both infections, 419 had chlamydia, 93 gonococci, and 41 both organisms. Thus 9 percent of chlamydia patients, and 31 percent of gonorrhea patients, were infected with both organisms.

Case-Interviewing

About four-fifths of chlamydia cases were interviewed for sexual partner information (Table 3). No case named a sexual partner of the same gender. The case-interview yield was similar to that obtained in gonorrhea cases.

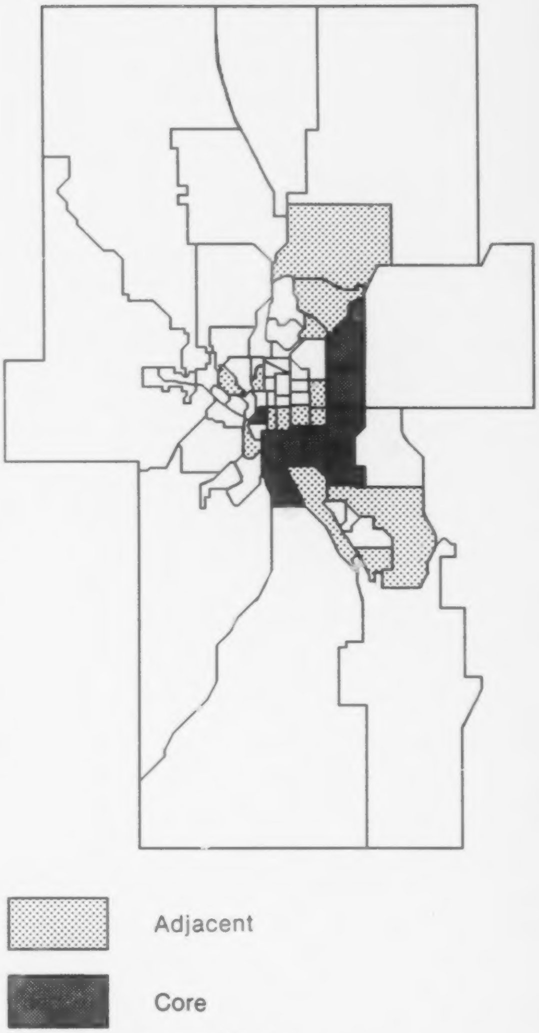

FIGURE 1—Gonorrhea Case Distribution
Public clinic cases (N = 291) in Colorado Springs in 1988: Census tract map showing core and adjacent areas (See Methods)

Had perfect tests been available to use on all examined contacts, the proportion infected would have been roughly the same for contacts to each disease, with chlamydia contacts exhibiting a slightly higher rate of infection in both men and women.

No ethnic differences were noted between chlamydia cases and their contacts.

Case-finding Efficacy

A total of 94 sexual partners had their infection newly identified as a result of case-interviewing and contact tracing (40 female and 54 male contacts). This result produces a 0.22 new case yield (94/419 interviews). Had perfect tests been available, an estimated 141 new cases would have been

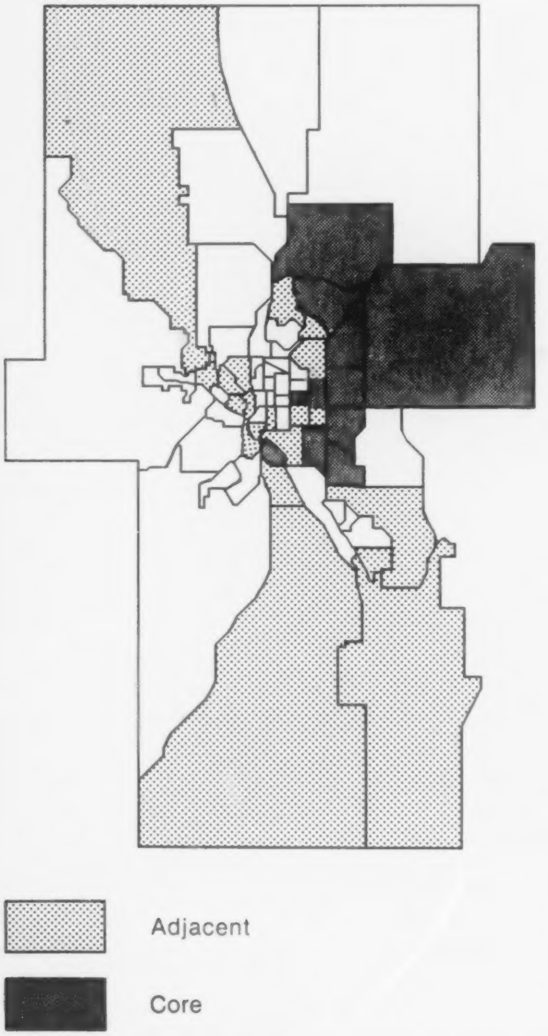

FIGURE 2—Chlamydia Case Distribution
Public clinic cases (N = 511) in Colorado Springs in 1988: Census tract map showing core and adjacent areas (See Methods)

identified, for a yield of 0.34. Thus, we estimate that public health workers need to interview three chlamydia cases and seek their sexual partners (about five), to remove one previously untreated, infected person from the disease pool.

Self-Referral Behavior

Of the 326 named sexual partners who newly were eligible for examination and were found, only 102 (31 percent) were successfully referred by the original chlamydia patient; the other 224 sexual partners required active intervention on our part to assure presentation. Of the 94 newly identified infected contacts, 34 (36 percent) were partner-referred. Black men were least likely to be partner-referred (17 percent), White men most likely (40 percent); Hispanic/Other men, 24 percent. Women were equally likely to be partner-referred (about 22 percent), irrespective of ethnicity.

Discussion

Although ours is not a population-based study of chlamydia prevalence, we found demographic differences between public clinic patients with chlamydia and those with gonorrhea, yet these two diseases infect columnar epithelial tissue and share the same mode of transmission. In Colorado Springs during 1988, public clinic cases of probable genital chlamydia and gonorrhea infection differed with respect to age, ethnicity, and domicile; clinically, little overlap between the two diseases was noted. The same is true for their sexual partners.

Sources of bias in the present study include testing and patient selection. Although neither the sensitivity nor specificity of the MicroTrak test was established locally, it is noteworthy that the estimated proportions of infected persons per sexual partner examined are nearly identical to those obtained in Sweden.[10] If the Swedish data are adjusted for the relative insensitivity of the McCoy cell culture test used in that study, we arrive at 0.84 (estimated) infections identified per Swedish woman contact examined and 0.61 per Swedish man contact, compared to 0.87 and 0.56 (estimated) respectively in our study (Table 3).

The tendency to test younger clients in STD clinic probably affected the age distribution of chlamydia cases. This bias is not likely to be substantial: age differences were also noted in the military cases we reviewed and these were not differentially selected. Bias stemming from incomplete testing for gonorrhea in the family planning clinic probably is minimal: characteristics of gonorrhea cases in this study closely match those from a previous report.[11] The insensitivity of chlamydia testing in asymptomatic men would create bias only in the case of differential insensitivity, which is not likely.

The typical chlamydia case tended to have infection detected as a consequence of screening or contact tracing, rather than via spontaneous presentation with symptoms. It is possible that asymptomaticity is one clue to observed differences in the community expression of these two diseases. In our experience men were at least twice as likely to be asymptomatic with genital chlamydia than with gonorrhea,[8] a ratio similar to that reported in Sweden.[10]

It is possible that sustained, vigorous gonorrhea control efforts on our part since the mid-1970s[12,13] influenced the observed distribution of chlamydia cases in our community. In Colorado Springs this population is principally White. As our interventions helped to decrease the gonorrhea burden from a high of about 2,000 cases in 1977 to about 1,000 cases in 1988, the proportion of cases accounted for by non-Whites increased from 39 percent in 1977 to 67 percent in 1988. This phenomenon may also explain the modest proportion of clinical overlap between the two diseases since gonorrhea is relatively well controlled in Whites locally.

We have demonstrated previously that gonorrhea is neither randomly nor evenly distributed in our sexually active populations[11] and that the basic setting for sexual aggregation and for sexual choices is the neighborhood. It is possible that in neighborhoods where the gonorrhea burden is high, the chlamydia burden may be lower than expected because of frequent exposure to antibiotic treatment on the part of gonorrhea cases and their sexual partners, especially since the introduction of dual treatment for gonorrhea and chla-

**Expected if laboratory tests were perfect. For chlamydia we use two-thirds as the observed sensitivity for men and women (see Methods) and for gonorrhea, 90% sensitivity for men and 80 percent for women.

The infection rate for women contacts to men with chlamydia may be underestimated because 21 of the 176 "examined" women were treated by their private physician without being tested.

mydia in the early 1980s.[6] Conversely, in neighborhoods where gonorrhea is an infrequent event, exposure to chlamydia may result in successful infection more often. In addition, entrenchment and perpetuation of chlamydia may be facilitated by its high rate of asymptomaticity. Age differences between chlamydia and gonorrhea patients may be accounted for by a tendency on the part of teenage women with chlamydia to select sexual partners close to their own age.

More research is needed to elucidate the factors that contribute to differences in the community distribution of these two closely related diseases. Meanwhile it is clear that public health intervention is crucial to the control of chlamydia infection in Colorado Springs. The disease is frequently asymptomatic, occurs often in populations that we are not encountering routinely in our standard STD outreach efforts (syphilis, gonorrhea, and human immunodeficiency virus infections), and the chlamydia-prone populations are only moderately successful at referring their sexual partners. Our data support a recent appeal to implement a "program of chlamydia control that is based on accurate diagnosis, contact tracing, appropriate therapy, and educational efforts to reduce risky behavior . . ."[14] Our first step is to encourage the reporting of chlamydia cases to public health officers.

ACKNOWLEDGMENT

A Small Area Simulation Approach to Determining Excess Variation in Dental Procedure Rates

PAULA DIEHR, PHD, AND DAVID GREMBOWSKI, PHD

Abstract: All small area analyses need to compare the observed variability in rates to that expected by chance alone, but the expected variability is usually not known. This paper uses patient-level data for five dental procedures to simulate the distributions of the summary statistics that are usually generated in such studies. These statistics are found to vary greatly even under the "null hypothesis" that all dentists are using procedures at the same rates. The simulated dentist rates are compared to observed rates obtained in a different study. These findings illustrate problems that can occur in small area analysis studies, and emphasize the importance of using statistical techniques that are appropriate for the data that are to be analyzed. Investigators should make every effort to obtain patient-level data, or at least to understand the underlying distribution of the number of procedures per patient, to avoid mistaking significant deviations from an incorrect model as evidence for significant variation among small areas. (*Am J Public Health* 1990; 80:1343–1348.)

Introduction

Small area analysis is a popular methodology in health services research. A typical study might calculate the utilization rate for a service in several small areas, compare the largest rate to the smallest, note that the difference is large, and attempt to explain the high variability as a function of service availability, physician uncertainty, and other variables of interest. The statistical methods used in such studies have been questioned by an author of this paper.[1]

A recent paper using computer simulation to examine the statistical properties of the most frequently used descriptive statistics[2] demonstrated that all of the usual descriptive statistics could be deceptive, showing large apparent variation when there was no more variation than would be expected by chance alone. A simple 2 × k chi-square test (classifying people in each of k communities into two cells, by whether they had or did not have the procedure) was an appropriate test for excess variability as long as each person could have the procedure at most once. However, the chi-square test could be deceptive; results would be "statistically significant" too often if an individual could have the procedure more than once. Simulation studies were recommended for these situations; this requires that the distribution of the number of procedures per person be known. Finally, it was pointed out that studies very similar to small area analyses were being conducted in other situations: e.g., a "small area" might be a hospital or a dental practice. This paper applies the small area simulation approach to a set of dental data, to determine if there is more variation in procedure rates among dentists than would be expected by chance alone.

Grembowski, *et al*,[3] calculated procedure rates for 200 dentists in general practice in four urban counties of Washington State from 1984 and 1985 dental claims of members of the Washington Education Association (WEA) and their dependents. The number of patients seen at least once in the two-year period ranged from 75 to 300 for the 200 dentists, as shown in Table 1.

TABLE 1—Number of Washington Education Association Patients Seen by each Dentist in Two Years

N of Patients Seen	N of Dentists
75–99	94
100–124	54
125–149	19
150–199	24
200–300	9

Procedure rates for each dentist were calculated by dividing the total number of procedures performed in a two-year period by the number of people seen at least once by the dentist during that period. Results were age-adjusted. Table 2 shows the substantial variability that was found among dentists: rates of oral examinations ranged from 10 per 1,000 patients to 3,543 per 1,000 patients. The coefficient of variation (the standard deviation divided by the mean) was 0.289. This seems like substantial variation. However, a good deal of variation can be expected by chance alone, even if the underlying rate of examinations per person is the same in each practice.[2] If "exams" were a binary variable, which a person could have once or never, it would be appropriate to use a 2 × 200 chi-square test to examine the null hypothesis that the probability of having an oral exam was the same in all practices.[2] However, it is obvious that many people have more than one examination in two years, which means that the chi-square test and the usual small area statistics are either inappropriate or have unknown distributions under the null hypothesis.

If the number of oral exams for each person were known, techniques could be developed to study whether there was excess variation. The data could be recoded so that each

TABLE 2—Observed Procedure Rates in 200 Dental Practices (number of procedures per 1,000 patients)

Category	Mean	SD	Min	Max	EQ	CV
Oral Exams	1617	467	10*	3543*	354.3*	.289*

Dr. Grembowski is Assistant Professor of Health Services and Dental Public Health Sciences at the University of Washington. This paper, submitted to the Journal September 12, 1989, was revised and accepted for publication March 8, 1990.

person was coded 1 if he had one or more exams, and 0 otherwise, and the chi-square statistic could be used; or, one could assume that the number of exams per person was approximately normally distributed, and perform an analysis of variance to study whether the average number of exams per person were different among the dentists. Unfortunately, the only data available for the Washington study were the rates per dentist of the various procedures. No patient level data were available. For these reasons, we attempted a simulation approach, discussed elsewhere in detail.[2] The goal is to determine what the distribution of procedures among the 200 practices would have been under the null hypothesis that no dentists were "high users" but, on the contrary, that all dentists performed the same number of procedures per person, on average. The simulation method attempts to determine how much variation among practices would be expected by chance alone. This is then used as a benchmark to determine whether the observed variation in Table 2 is important.

Methods

Data

A different data source was used to obtain information about the distribution of procedures at the patient level. Annual dental utilization data were obtained for 12,897 insureds from a random sample of adults and children covered by Pennsylvania Blue Shield dental insurance in 1980. These data have been analyzed elsewhere.[4,5] The 5,912 people with no dental visits in 1980 were eliminated from the data set. Appendix 1 contains frequency distributions for five dental procedures—oral exams, fillings, simple extractions, root canals, and full-mouth periodontal scalings. (For example, 2,764 patients had no oral exams, 2,717 had one exam, and six people had 12 oral exams in one year.)

Fitting the Pennsylvania Data

We first attempted to fit the Pennsylvania data to the Poisson and negative binomial distributions.[6] If a known distribution was appropriate, we could use it to generate random data for the simulation. Clearly, none of the data are normally distributed because of the long tails and the high number of observations clustered at zero. The Poisson distribution is not likely to fit the data because a Poisson process assumes that procedures occur independently, which is probably not the case for dental procedures. The negative binomial distribution assumes that each person uses procedures with a Poisson distribution, but that each person has a different Poisson parameter, distributed according to a gamma distribution.[6] This distribution was considered because it has longer tails than the Poisson distribution.

We estimated the parameters of the Poisson and negative binomial distributions using the maximum likelihood procedure.[6] This yielded expected numbers which were compared to the observed numbers with the chi-square goodness of fit test.[7] Neither distribution provided an acceptable fit for the number of oral exams or for fillings. The negative binomial distribution did provide an adequate model for the number of extractions, root canals, and scalings.

The following simulation work did not assume any mathematical distribution, because there was none that worked for all the data. Rather, data were generated directly from the empirical distributions, as described below. Future work in simulating procedure rates for extractions, root canals, and scalings might use the negative binomial distribution to generate random data, however.

Simulation of Utilization Rates

Our goal was to develop a simulation model to assess the amount of variability that would have occurred among the dental practices by chance alone if the null hypothesis (that all dentists use procedures at the same underlying rate) is true. We generated 100 different simulated sets of procedure rates, in which the null hypothesis was true.

For each of the 200 dentists, a uniform random number between 0 and 1 was generated for each patient in that practice (e.g., for a dentist with 75 patients, 75 random numbers were generated). Each of these numbers was compared to the cumulative distribution in Appendix 1. For example, 2764/6985 or 39.5 percent of the people had no oral exam; 78.46 percent had 0 or 1 exam; 97.7 percent had 0, 1, or 2 exams, etc. For each random number, if it was less than .395, the patient was assigned 0 exams; if between .395 and .7846, the patient was assigned one exam, etc. Thus, on average, the number of exams per patient match the distribution of Appendix 1, but the distributions were somewhat different for each dentist.

After the number of exams were generated for all 75 patients in the first practice, the exams were summed, multiplied by 2 (see discussion section) and divided by 75 to provide a simulated two-year rate of oral exams for that dentist. This was then continued for all 200 dentists, which generated 200 different simulated examination rates. Next, the minimum rate, the maximum rate, the extremal quotient (EQ, ratio of the maximum rate to the minimum), the coefficient of variation, and other statistics explained in the results section were calculated. This process was repeated 100 times to give, for example, the "average" maximum rate, or the 95th percentile of the maximum rate, under the null hypothesis that each practice has the underlying distribution of examinations shown in Appendix 1.

Results

Mean Procedure Rates

Table 2 shows the observed results, and Table 3 shows the simulated results. The first column in Tables 2 and 3 is the estimated mean number of procedures per 1,000 patients. Recalling that the two sets of numbers arise from different data sets, there is fairly good correspondence on the rate of oral exams (1,725 versus 1,617), root canals (55 versus 44), and full mouth scaling (34 versus 23). There is very poor agreement on fillings (2,123 versus 889) and for simple extractions (211 versus 119). This may be due to differences in billing practices between Pennsylvania and Washington Dental Service—the carrier for Washington Educational Association. There are probably also socioeconomic differences between the Washington and the Pennsylvania patients. These differences are considered further below.

TABLE 3—Simulated Procedure Rates (number of procedures per 1,000 patients)

	Rate	Minimum		Maximum		EQ	
	Mean	Mean	5%	Mean	95%	Mean	95%
Oral Exams	1725	1260	1136	2304	2537	1.8	2.1
Fillings	2123	1195	974	3422	3897	2.9	3.4
Extractions	211	30	0	529	667	17.5	30.1
Root Canals	55	0	0	259	342	—	—
Scalings	34	0	0	227	316	—	—

EQ = Maximum/Minimum
Based on 100 iterations per procedure.

Maximum and Minimum

The simulated minimum and maximum are shown in Table 3. For example, on average, the lowest rate of oral exams was 1,260 per 1,000 patients, and the highest rate was 2,304 per 1,000, even though the underlying rate for all dentists was 1,725. Thus, an observed minimum rate near 1,260 or a maximum rate near 2,300 would not be an indication of excess variability among practices. Table 3 also shows the simulated 5th percentile of the minimum and 95th percentile of the maximum. That is, 95 percent of all minimum values are above 1,136, and 95 percent of all maximum values are below 2,537.

The observed minimum rates for oral exams, shown in Table 2, can be thought of as extremely low, since 10 is substantially below 1,136. The same is true for fillings. The minimum for the other procedures is 0 for both the observed and the simulated data. Comparing the maximum values of Table 2 to the 95th percentiles in Table 3, the maximum rates for oral exams and for full mouth scaling are higher than would be expected by chance alone, but the other maxima are not particularly high.

Extremal Quotient (EQ)

Table 3 shows the simulated average value and the 95th percentile of the EQ (maximum divided by minimum). For oral exams, one would expect an EQ of about 1.8, and values above 2.1 (the 95th percentile) would be considered particularly high. For fillings, a ratio of 2.9 is expected, and 3.4 would be considered high For extractions the minimum value was 0 in 10 percent of the simulations, and the EQ could not be computed. For the remaining 90 percent, the expected EQ was 17.5 and the 95th percentile of the EQ was 30.7. The EQ is infinite for root canals and scalings, as the minimum is always zero. In Table 2, the observed EQ could be computed only for oral examinations and fillings. Both of the observed EQs are much larger than the 95th percentile of the EQ distribution, indicating that the null hypothesis that all dentists had the same rates is probably not true. The variability in the rates is due in part to some dentists having much *lower* use of procedures than would be expected.

Coefficient of Variation (CV)

Table 4 shows that the 95th percentile of the simulated CV (standard deviation over mean) for oral exams is 0.115, as compared to an observed value of 0.289 shown in Table 2. The observed variation is thus higher than would have been expected by chance alone. All of the observed CVs are considerably above what would have been expected. Therefore, the null hypothesis probably is not true, and there are some dentists who use procedures at different rates from the others.

TABLE 4—Simulation Results—Other Summary Statistics*

Tabled 95th Percentile			233	3.84	1.17

*CV is the coefficient of variation and SCV is an estimate of the systematic component of the variation, defined in the text. Chi-square with 199 degrees of freedom is 2 × k chi-square assuming that each procedure is a person. Chi-square with 1 df is the test for a particular practice (see text). F is the F statistic that arises from a 1-way analysis of variance. Tabled 95th percentiles are taken from tables of the chi-square and F distributions.

Based on 100 iterations per procedure.

Systematic Component of Variation (SCV)

Table 4 shows some other statistics commonly used in small area analysis, which were not calculated for the Washington data. They are included for completeness. The SCV has been proposed by McPherson and Wennberg as a test for excess variability among small areas.[8] The formula is:

$$SCV = (1/\mathrm{k})\ [\Sigma((\mathrm{O}_i - \mathrm{E}_i)^2)/\mathrm{E}_i^2 - \Sigma(1/\mathrm{E}_i)]^*\ 1000.$$

There is an F-test associated with this statistic, but it is not often used. The SCV was derived under the assumption of Poisson rates, which is not appropriate here. The data in Table 4 illustrate further what has been shown elsewhere[2]; that is, that the SCV can take on very large values, even when there is no underlying variation among the small areas. In addition, it becomes larger as the mean rate becomes smaller. Thus, it would be unwise to use the SCV alone as a descriptive statistic in this situation.

Chi-Square

Two chi-square tests have been used in small area analyses. One test is a 2 × 200 chi-square test, which assumes that each person received a procedure at most once, calculates the number not receiving the procedure as "population size minus the number of procedures," and creates a 2 × 200 table. This is clearly inappropriate in our situation, since many people had more than one procedure. In fact, the 95th percentile of this chi-square statistic is negative for oral exams and fillings, because the expected numbers of people who did not have the procedure are negative for some dentists (for example, there are more fillings than patients). A chi-square value greater than 1,000 would be needed to demonstrate "significance" for the last three procedures, as compared to the tabled 95th percentile of the chi-square with 199 degrees of freedom, which is 233.

Another test which is proposed in these situations is a 1 degree of freedom chi-square test of the hypothesis that a particular dentist has a rate significantly different from what would have been expected. The expected number of procedures would be the grand rate (e.g., 1,725 oral exams per 1,000) times the number of patients (e.g., 75, for an expected rate of 129 exams). If the observed rate were, e.g., 155, the chi-square statistic would be $X = (O - E)^2/E = (155 - 129)^2/129 = 5.2$. This is much higher than the usual critical value of 3.84 for the chi-square distribution with 1 degree of freedom. However, Table 4 shows that the 95th percentile of chi-square statistics in this situation is 7.28, meaning that 5.2 is not a particularly large value. The 95th percentiles for the other dental procedures are even larger, ranging from 13 to 27. Thus, the simple chi-square test, to look for outliers, could be extremely deceptive in this situation, indicating significant variation when a practice was operating, on average, like all other practices. Or, put another way, 16 percent of the chi-square statistics would have been greater than 3.84 for oral examinations, giving a Type I error of 16 percent rather than the commonly accepted 5 percent level. The other Type I errors are 47 percent for fillings, 30 percent for extractions, 28 percent for root canals, and 19 percent for scalings. If these data were being used to identify outlying dentists, far more than 5 percent would be incorrectly labeled as over-providers. This discrepancy occurs because the data violate the essential property required for the chi-square test:

that the counts be independent (or, that the distribution of counts per person follow the Poisson distribution).

There is another problem with this chi-square test, which is that it ignores multiple comparisons. If a chi-square test, even using the correct 95th percentile, were performed for all 200 dentists, about 5 percent (10 practices) would be judged to have excessive utilization rates by chance alone. The probability that no dentist was classified incorrectly is $.95^{200}$ = .00004. Thus, the experiment-wise Type I error is almost 1.0. This might be adjusted for by using an alpha level of .05/200 = .00025 instead of alpha = .05. This would require comparing the observed chi-square values to the 99.975th percentile of the distribution (about 17.17 instead of 3.84 in this situation).

Clearly, the combination of these two problems (that the chi-square statistic does not follow the chi-square distribution, and that there are multiple comparisons) will tend to yield extremely high observed chi-square values even in the null case. Users who are not aware of this problem risk labeling small areas as outliers that are not extreme at all. We have seen examples in which a large percent, or even *all* of the small areas being considered, were labeled as outliers based on this test![9]

Analysis of Variance (F-test)

The 95th percentile of the F distribution is given in Table 4. This statistic would have resulted if we had performed an analysis of variance to detect a difference among the 200 dentists in the mean number of procedures per person. Analysis of variance requires having patient-level data, so that the variation among people can be computed. This was not available in the Washington data, but could be computed from the Pennsylvania distributions. The 95th percentile for an F distribution with 199 and infinite degrees of freedom is 1.17 if the null hypothesis is true. This is close to the simulated F values for the dental procedures (1.22, 1.13, 1.17, 1.19, 1.20), showing that analysis of variance would have been appropriate if patient-level data had been available, even though the data in Appendix I are far from normally distributed. (We used only 100 iterations, so the percentiles might be even closer than is shown.) If the data are not available at the individual level, to permit analysis of variance, it will be necessary to perform a simulation study to determine whether there is more variability than would be expected by chance alone.

Adjusting the Pennsylvania Rates

It is unfortunate that some of the average rates were so different in the Washington and Pennsylvania data sets. This suggests that some of the "significant" variation detected could have been caused not by excess variation but because the Washington data were being compared to the wrong underlying distribution. To examine this possibility we standardized the results, so that the average simulated rate would be the same as the average observed rate. Specifically, we multiplied the simulated rates by a constant factor (e.g., for oral exams 1617/1725 = 0.937 so that the simulated mean would be 1617). This has the effect of multiplying most of the values in Tables 3 and 4 by a factor less than one (0.937 for oral exams). (The EQ, CV and F values would be unchanged). The observed data would then be as extreme or even more extreme, if compared to these adjusted tables. All of the observed maxima would be larger than the adjusted 95th percentile except for root canals.

Discussion

The intent of this paper was to demonstrate that small area analysis issues were similar to those in detecting excess variation in other settings, and in particular to illustrate the simulation approach. Both the findings and the methods merit some discussion.

If we assume that the underlying distribution of procedures is about the same in the Washington and Pennsylvania data, the simulation method has demonstrated that there was excess variability for oral examinations and full mouth scaling. The other procedures also showed excess variability, although not as unequivocally.

There are some shortcomings to these results, and also to the methods that we used to obtain them. The Washington population was a fairly homogeneous group of middle-class patients. The Pennsylvania Blue Shield data were from a random sample of all insureds, who varied by social class. The differences between the two study populations may explain why the mean rates for the rehabilitative services in Table 3 were higher than those in Table 2. Also, Pennsylvania had better coverage for fillings than did the Washington contract, which may account for the discrepancy in filling rates between Tables 2 and 3.

The estimated rates from one year of Pennsylvania data were multiplied by 2 to give two-year rates for comparison with the Washington data. This is not quite appropriate, as it assumes that non-users in the first year would not have used any services in the second year. The correct multiplier is between 1.08 and 2.0 (details from authors). The "2" was chosen as an upper bound, to provide as much variability as possible. If 1.08 had been used, all of the observed maxima would have been above the 95th percentile.

No effort was made in either data set to remove people who were not covered for the entire period of time. If a person was insured for only one month of the two-year period, the rate was calculated as though the person had been at risk for the entire 24 months. This would tend to lower the rates, and would lower them more for the Washington data than for the Pennsylvania data, since the time period was longer for Washington. This may explain some of the differences in the two data sets.

We did not model one aspect of the variability—that a different number of patients might have been seen in different two-year periods. Age and sex differences were not incorporated in the simulation, as the Washington data had already been age standardized, and sex is not an important determinant of use in insured populations.[4,5] We showed elsewhere[2] that this was a reasonable way to proceed. Finally, the estimated means and percentiles are not completely accurate, as there were only 100 simulations per procedure.

Once excess variability has been established, it is appropriate to examine reasons for this variability. Grembowski, *et al.*,[10] have shown that structural features of the practice, such as its age and size, explain some of the variation in the rates.

Although not completely satisfactory, the simulation approach has provided support for the finding of excess variability among dentists. Utilization review programs operated by dental insurers are often implemented to identify dentists who have high procedure rates. The insurer may, for example, intensify review of the dentist's claims as a means of reducing the dentist's rate. Our results indicate that insurers need to determine whether excess variability exists for a given procedure before a dentist is labeled as providing "too many" services. Of equal importance, if excess variability is detected, dentists with the lowest rates may be underutilizing appropriate services.[3] Therefore, insurers should target utilization review at both ends of the rate distribution.

The methodology of this study is applicable in other situations. We used the simulation method to examine the characteristics of small area analysis statistics applied to dental practices instead of geographic areas. Dental practices have smaller numbers of patients in each "small area" and some of the procedures are applied multiple times to the same person. The distributions of root canals or scalings, which are rare, are more similar to the distribution of the number of hospital admissions for a particular diagnosis, which is often considered in small area analyses. The main results of this study have to do with the underlying distribution of services, the properties of several descriptive statistics, and various hypothesis testing procedures.

None of the distributions of services in Appendix 1 had a Poisson distribution. This is important because several approaches are now being used in the small area literature which assume that the underlying distribution is Poisson: the 1 df chi-square test and the SCV were derived under these assumptions[8] and some regression approaches model deviations from the Poisson distribution.[11,12] In all of these methods, statistically significant departures from the Poisson distribution are taken as evidence that there is unexplained variability among the small areas. However, as shown here and elsewhere,[2] the underlying distribution at the person level may not have a Poisson distribution, and finding "significant" variation is as likely to be caused by this fact as to represent excess variation among the small areas. Unless there is evidence that the underlying distribution is Poisson (e.g., that a person cannot have more than one of the procedures of interest) this is an inappropriate inference.

Tables 3 and 4 demonstrate that a considerable amount of variability can be expected among small areas by chance alone, and that it is dangerous to "eyeball" descriptive statistics as a test for excess variability. The minimum and maximum rates, and the extremal quotient, could vary considerably under the null hypothesis. The coefficient of variation and the systematic coefficient of variation also vary substantially, and tend to be larger for the less prevalent procedures (i.e., higher for root canals and scaling than for oral exams and fillings). It is common to compare CVs or SCVs across several procedures, and to claim that those with the largest coefficients represent "practitioner uncertainty." If we had done this with the data of Table 4, we would have "found" that there is less certainty about root canals and scaling than about oral exams and fillings, even though under the simulation model all dentists used procedures at exactly the same underlying rates! It is inappropriate to infer differences in "certainty" based only on CVs or SCVs if procedures have different mean rates.

Several tests of the hypothesis that there is underlying variation among the small areas have been developed. One is a 2 × k chi-square test which is appropriate if a person can have the procedure of interest at most once (e.g., death, removal of an organ). This procedure failed for the data of this study, even for procedures such as root canals, where the assumption that few people had more than one per year would have seemed "reasonable." Thus, the assumptions of this test must be examined with care.

The second chi-square test, which purports to test whether an individual dentist or small area is an "outlier" (observed significantly different from expected) was also shown to be inappropriate first, because the data do not meet the underlying assumption of a Poisson distribution, and second, because the problems of multiple comparisons are ignored. It is very important that this test be used correctly, since it singles out particular areas or dentists as outliers, and may have deleterious effects.

A third test which is sometimes proposed is a simple analysis of variance. The simulation results of Table 4 show that it would have been appropriate for these data, if data had been available at the patient level. (Such data may be difficult to obtain, as there must be a unique patient identifier to permit ascribing multiple procedures to a person.) If investigation of patient level data showed that they were inappropriate for analysis of variance, logarithmic or other transformations could be attempted.

The simulation method we have proposed has so far been used only in the null situation. The power of the various procedures to detect true underlying variation has not been studied; it should be studied. It is possible that tests based on the CV, for example, would be more powerful than other types of tests. More methods research is needed in this area.

The major lesson of this paper is that it is important in small area analysis to understand the underlying distribution of services, at the patient level, to avoid mistaking misspecification of the underlying model for statistically significant excess variability among small areas.

*This is a sample of 12,897 people enrolled in Pennsylvania Blue Shield in 1980. Of these, 5,912 had no dental procedures in this period. These were removed from this table to match the WEA data more closely. (WEA data included only people who used one or more procedures in two years). Thus, the distributions represent the utilization of 6,985 people who had at least one dental procedure in one year. Only 3,772 of the patients had coverage for full-mouth scalings.

Medical and Psychosocial Factors Predictive of Psychotropic Drug Use in Elderly Patients

L. Douglas Ried, PhD, Dale B. Christensen, PhD, and Andy Stergachis, PhD

Abstract: The purpose of this study was to investigate medical and psychosocial factors that may be used to identify patients at risk of psychotropic drug use. Population-based surveys were completed by 278 elderly health maintenance organization (HMO) patients in August 1984. Physical and mental health status and social support were measured in the survey. Automated prescription records from the year prior to and the year after the survey were linked to data from the survey. Patients received 737 prescriptions for psychotropic drugs during the two-year period under study. Doxepin (20.2 percent), flurazepam (15.2 percent), and diazepam (14.8 percent) were dispensed most frequently. Nearly 30 percent of the patients received a prescription for at least one psychotropic drug during the two-year period, and 14 percent received at least one prescription during both years. Three significant predictors of subsequent psychotropic drug use were: prior use (odds ratio = 17.2, 95% CI = 6.25, 47.33), the number of physical impairments (OR = 1.73, 95% CI = 1.05, 2.84), and the respondent's rating on the Alameda Health Scale (OR = 1.65, 95% CI = 0.99, 2.75). Patients' self-reported mental health status and sociodemographic characteristics were not significant predictors of subsequent use. (*Am J Public Health* 1990; 80:1349–1353.)

Introduction

Patients who are 65 years or older are at risk of incurring drug-related problems, in part, because they use drugs more frequently and more intensively than younger patients.[1] They are also more likely to have one or more chronic diseases that require drug treatment, often more intensive drug treatment.[2] Psychotropic drugs are among the most frequently consumed drugs and are among the most likely to cause problems for older patients.[3] National estimates indicate that 15 percent of ambulatory males and 24 percent of females over age 65 used a psychotropic drug in 1977.[4]

Once elderly patients begin using a psychotropic drug, use may continue for an extended period of time. One study reported daily use for 12 months or more by 38 percent of antidepressant users and 15 percent of antianxiety users.[5] Another study reported that about 60 percent of elderly patients who obtained a prescription for a psychotropic drug in the preceding year also received one in the subsequent year, and the highest prevalence of extended use (i.e., over 10 years) was among patients 65 years and older.[6]

Psychotropic drug use has been repeatedly demonstrated to be associated with physical and central nervous system side effects, including reduced mental functioning,[7] addiction,[8] sleep apnea and sleep disturbances,[9] and hip fractures.[10] Correlates of psychotropic drug use include female gender,[5,11–13] psychological and physiological conditions,[14–16] and lack of a supportive social network.[17,18] No definitive and persistent associations have emerged among marital status, economic status, and class differences in the use of mood modifiers.[11]

Most studies investigating psychotropic drug use have been retrospective and have relied primarily on self-reported psychotropic drug use.[5,15,19–21] Few studies have determined patients' psychosocial characteristics during the prior year and then examined their subsequent psychotropic drug use patterns.[12,22] The purpose of the present study was to examine a group of elderly patients for predisposing medical, physical, social, and psychological factors that explain and predict their subsequent psychotropic drug use.

Methods

The Setting

The study was conducted at Group Health Cooperative (GHC) of Puget Sound, a staff model, non-profit health maintenance organization (HMO) serving approximately 340,000 members in western Washington State. A population-based survey of an age and sex-stratified random sample of 1,432 GHC adult enrollees ages 18 years and older was conducted during August 1984. Enrollees over age 65 were oversampled in order to increase the accuracy of the estimates for this age group. A description of the survey has been reported earlier and includes a comparison of the sample with the Seattle Standard Metropolitan Statistical Area (SMSA) population.[23] Completed surveys were obtained from 79 percent of the original sample. The response rate increased to 81 percent after persons were removed from the denominator who were either deceased or who were no longer enrolled in GHC at the time of the survey. The sample for the present study was a subset of 278 persons over 65 years of age who completed the survey.

In addition to their survey data, prescription records for these elderly patients were obtained from GHC's automated prescription files. Data have been collected on each prescription filled at GHC since 1977 and includes individual patient's medical history number, drug name, strength, dosage form, therapeutic category, legend status, date dispensed, and prescriber. Psychotropic drugs were an out-of-pocket expense during the study period, provided to GHC enrollees at cost. Previous studies have shown the pharmacy files are very complete and accurately reflect the actual drug use experience of GHC enrollees.[24,25]

Subsequent Psychotropic Drug Use

Subsequent psychotropic drug use was determined by an examination of the prescription records for the one-year period after the survey (September 1, 1984 to August 30, 1985). Patients were classified as users or non-users of psychotropic drugs. Users were defined as patients obtaining one or more prescriptions for an antidepressant, anxiolytic, or sedative-hypnotic drug the subsequent year. Drug prod-

ucts were classified according to the American Medical Association Drug Evaluations.[26] A second level of use was measured by counting the number of psychotropic drug prescriptions each patient received during the year after the survey, a simple indicator of the frequency or intensity of use.

Predictor Variables

Predictor variables included the patients' psychotropic drug use during the one-year period prior to the survey, sociodemographic characteristics, social support, and medical, psychological and physical health status. Sociodemographic characteristics included the patients' marital status, living situation, age, educational attainment, income, and gender. Mental health status and social support measures were obtained primarily from the Rand Health Insurance Survey[27] and included measures of depressive symptomatology, positive outlook, and closeness/completeness of relationships.

The first physical health status measure was based on whether patients reported having suffered from each of 17 specific medical conditions or physical ailments in the preceding 12 months (1 = yes; 0 = no); the measure was the sum of all the yes responses. Patients were also asked if their physical condition sometimes interfered with (1 = yes; 0 = no): a) dressing, feeding or moving around, b) climbing stairs or getting outdoors, c) ability to work because of some illness or injury, d) changing or cutting down the kind of work, or e) cutting down or causing them to stop any other activity such as hobbies or social activities; the total number of yes responses constituted this measure. Finally, self-reported health status was measured by asking patients to compare their own health to others' their age (1 = excellent; 2 = good; 3 = fair; and 4 = poor). Self-reported health status has been shown to be related to objective measures of health status.[28–30]

The Alameda Health Status Scale[31] was also used as a composite measure of physical health status. Its categories are based on questions related to disability, impairments, chronic conditions, symptoms and energy levels, i.e. severe (1) to no disabilities/impairments and a high energy level (7). Lower scores have been shown to be associated with poorer health outcomes (e.g., higher mortality risk and long-term psychotropic drug use).[31,32]

Statistical Analysis

Psychotropic drug users and non-users were compared on each of the predictor variables to determine if there were significant bivariate differences using *chi*-square and t-tests. Logistic regression techniques were used to derive an estimate of the natural logarithm of the odds of using psychotropic drugs in the next year because the predictor variables included both categorical and continuous variables[33–35]. Proportional effects were calculated from the logistic coefficients using the mean of the dependent variable as the point of comparison. Proportional effects are interpreted as the predicted change from the point of comparison in the proportion of cases belonging to category 1 (e.g. psychotropic drug users) rather than in category 0 (e.g. non-users) for a one-unit change in the predictor variable.[36,37] A residuals regression approach was taken. Predictor variables were entered into the equation in a hierarchical fashion in order to determine change in the likelihood of psychotropic drug use over time. Prior psychotropic drug use was entered first. The sociodemographic variables were entered in the second step and the psychosocial variables were entered in the final step. The improvement of fit in the logistic models was determined by evaluating the change in the log-likelihood statistic for each step. Finally, multiple regression was used to examine the relationship between the predictor variables and the number of psychotropic prescriptions obtained during the subsequent year.

Results

The 278 patients received 737 prescriptions for psychotropic drugs during the two-year period. Anxiolytic prescriptions accounted for 40.9 percent of the prescriptions dispensed (diazepam, 15.2 percent; meprobamate, 6.9 percent; alprazolam, 4.3 percent; all others, 14.5 percent). Antidepressant prescriptions were the next most frequently dispensed (35.8 percent) and included doxepin (20.8 percent), amitryptiline (9.8 percent), trazadone (3.5 percent) and all others (1.7 percent). Finally, sedative-hypnotics accounted for 23.3 percent of the psychotropic drug prescriptions dispensed (flurazepam, 15.6 percent; triazolam, 7.2 percent; pentobarbital, 0.5 percent).

Over 30 percent of the patients obtained at least one prescription for a psychotropic drug during the two-year period studied (Table 1). Nearly 23 percent of the patients had between one and 10 prescriptions filled, whereas over 8 percent of them received 11 or more prescriptions (range 0 to 39 prescriptions per patient). When only patients obtaining one or more psychotropic prescriptions were examined, they averaged nearly nine prescriptions per patient and over 60 percent of the patients that obtained a psychotropic prescription during the first year obtained another during the subsequent year. Nearly 53 percent of the patients who obtained a single prescription during the two-year study received an anxiolytic and 33 percent received a sedative-hypnotic. On the other end of the continuum, one patient received 39 psychotropic prescriptions (34 antidepressant prescriptions

TABLE 1—Frequency and Intensity of Psychotropic Drug Use

			200 or more	37	5.0
TOTAL	278	100.0	TOTAL	737	100.0

and five anxiolytic prescriptions) and another patient received 36 prescriptions (all for anxiolytics).

Table 2 shows the results of the comparisons on each of the sociodemographic and health status predictor variables during the subsequent year between users and non-users of psychotropic drugs. The average user was nearly two years younger than the average nonuser. Psychotropic users reported that their physical condition interfered with more of their daily activities, had more self-reported medical conditions, had a less positive outlook on life, and, according to their own reports, were in somewhat poorer health. It is interesting to note that while self-reported health status of users was significantly lower than that of non-users, it was still in the "good" to "fair" range.

Multiple logistic regression results showed that prior drug use was the most important predictor of subsequent use (Table 3). A patient using a psychotropic drug during the year prior to the survey was 17.2 times (95% CI = 6.25 to 47.33) more likely to be a user during the year following the survey when compared to a non-user in the year before the survey. Stated another way, psychotropic drug use during the year before the survey increased the probability of being a user in the year after the survey to over 80 percent. The sociodemographic variables did not contribute to the prediction of subsequent use with the prior drug use variable in the model. For each additional daily activity interfered with, or for each additional unit increase on the Alameda Health Index, the probability of using a psychotropic drug increased 9.9 and 8.9 percent, respectively. The two mental health status variables (depressive symptomatology and positive outlook) were not significant when use in the prior year and physical health status were simultaneously controlled. Addition of the psychosocial and physical health status variables as a group did not significantly improve the fit of the equation over just prior use alone. In a separate analysis, the sociodemographic, psychosocial and physical health status measures were entered first into the equation (as a proxy for psychosocial and physical health status *prior* to psychotropic drug use in the year before the survey). Adding these variables first into the equation did not improve the fit of the model over the constant alone (change in *chi*-square goodness-of-fit = 5.17, 11 df). When drug use in the prior period was next added to the equation, the fit of the model improved (change in *chi*-square goodness-of-fit = 35.54, 1 df).

The only significant predictor of the number of psychotropic prescriptions obtained during the year following the survey was the number of psychotropic prescriptions obtained in the year before the survey (Table 4). The large positive relationship between the prior year's use and the subsequent year's use confirms that patients obtaining a larger number of prescriptions in the prior year are more likely to obtain a relatively larger number of prescriptions in the subsequent year.

Discussion

Our results show that elderly patients at the most risk of receiving a prescription for an anxiolytic, antidepressant or sedative-hypnotic drug in the following year were those who had used one in the previous year. Patients at greater risk were also more likely to be in somewhat poorer physical health and to have their daily activities interfered with to a somewhat greater extent. Patients' sociodemographic characteristics and measures of their mental health status were not significant predictors of subsequent psychotropic use. The frequency or intensity of subsequent drug use was also closely associated with the previous year's experience.

*Residuals analysis identified three outliers. The adjusted R^2 increased to 0.57 when the three outliers were eliminated.

Our finding that psychotropic drug use is independent of patients' physical and mental health status is consistent with the work of others.[38] There was also evidence of an association between physical disorders and the likelihood of any use, but not with the number of psychotropic prescriptions obtained during the subsequent year.

One reason for the predominant role of prior drug use as a predictor of later use, especially when compared to the findings of previous studies, may relate to the differences in data collection methods. In most of the previously cited retrospective studies, patients were asked to recall their psychotropic drug use during a period prior to collection of the psychosocial information. In terms of cause and effect, this more closely represents the notion that the psychotropic drug caused the psychosocial condition, not vice versa. In this study, we collected psychotropic drug use from prescription records before and after assessment of patients' sociodemographic and psychosocial characteristics.

Limitations to the study design exist that may constrain interpretation of the data. Psychotropic drug users were identified exclusively by automated pharmacy records. The GHC pharmacy data base provides a reasonably complete record of receipt of drugs; however, patients' actual consumption was unconfirmed. In addition, patients' sociodemographic characteristics and physical and mental health status data were obtained exclusively by self-reports.

Further work is needed to examine predictors of individual psychotropic drug categories. Small numbers of users prohibited such an analysis in this study. The sample size also influenced the time interval chosen for the present study. It would be beneficial to examine whether patient characteristics and mental health status were more important if the time interval were shorter than one year.

Another limitation of these data is the nature of the sample. The statistical findings are governed not only by its size, but also by the distribution of the variables within the sample. The distribution may differ in another sample. Therefore, caution should be used when generalizing our findings beyond the population of elderly patients from where our random sample was drawn.

Psychotropic drugs are often legitimately used for short-term treatment of physical disorders associated with normal aging; however, long-term use has been questioned.[39] Long-term psychotropic drug taking may be a learned behavior directed at helping elderly patients deal with chronic physical and emotional problems or reducing anxiety attacks and physical symptoms associated with withdrawal syndrome.[39–41] Prescription for a psychotropic drug may also serve to diminish physicians' frustration in treating the many ambiguous conditions associated with normal aging and to appear supportive to the patient.[38,42–43] Examination of the specific reasons for prescribing psychotropic drugs was beyond the scope of this study. However, we did document a pattern of continued use among a small portion of the elderly population that could not be explained or predicted by the level of patients' sociodemographic, mental and physical health status, and social support.

ACKNOWLEDGMENTS

Portions of this paper were presented at the 5th International Conference on Pharmacoepidemiology in Minneapolis, MN, September 1989. The authors would like to acknowledge the contributions of David C. Pearson, Ph.D., who developed and conducted the Health Risk Survey, and Virginia Immanuel, who assisted in the preparation of the data for analysis. The Association between Type A Behavior and Change in Coronary Risk Factors among Young Adults

Thomas F. Garrity, PhD, J. Morley Kotchen, MD, Harlley E. McKean, PhD, Diana Gurley, PhD,
and Molly McFadden, MS

Abstract: The association of Type A/B behavior pattern and changes in blood pressure, total serum cholesterol, serum triglyceride, body mass, and smoking was estimated in a cohort of 375 young Black and White men and women from a rural county in Central Kentucky between 1978–79 and 1985–88. Type A participants experienced significant increases in systolic (2.90 ± 1.29 mmHg) and diastolic (3.80 ± 1.17 mmHg) blood pressure and in cigarette smoking (3.26 ± 0.89 cigarettes per day) over the eight-year follow-up period, but Type B participants experienced no change. Type A and B individuals showed similar changes in total serum cholesterol, serum triglyceride, or body mass. Differences between behavioral types in blood pressure were present for women but not men, and for Blacks but not for Whites. These findings suggest a possible significance of the Type A pattern for the development of cardiovascular risk of young adults. (*Am J Public Health* 1990; 80:1354–1357.)

Introduction

Cardiovascular epidemiology has established blood pressure, serum cholesterol, and smoking as the most powerful and consistent predictors of coronary risk in middle age and older adults. Studies of children suggest that coronary risk factors are already present at early ages,[1,2] but relatively little epidemiologic data exist on the coronary risk status of young adults, especially those who have recently completed physical growth as they begin to enter typical adult roles in this society,[3] a phase characterized by changes in lifestyle and responsibility. The student becomes a worker, the single person a spouse and parent, with changes in eating, drinking, sleeping, and exercise.

The style of coping with these challenges may have a bearing on level of life stress and, through it, on markers of coronary risk. Type A, coronary-prone behavior pattern is believed to relate to risk for coronary heart disease.[4] We followed a sample of men and women from small town and rural backgrounds from an average age of 21 years to an average age of 29 to determine whether Type A/B behavior pattern is associated with change in coronary risk factors. Previously, we have shown clustering of risk factors in individuals in this population.[5]

Methods

The sample for the present study was derived from a 15-year longitudinal cohort study of young adults in a rural county of the Central Kentucky Bluegrass. In 1973, all high school students of Bourbon County, Kentucky (N = 1,142) were assessed for their blood pressures, body weights, and heights, as well as a few other demographic characteristics. Students' ages ranged from 14 to 19 years.

In 1978–79, a sample (N = 472) was drawn from the original study population to include the 20 percent of young adults who had the highest and lowest systolic blood pressure readings when they were teenagers in 1973. Because some of the subjects had not yet achieved adult growth at baseline, all of the subjects who were less than 16 years old in 1973 were also contacted for re-examination in 1978. Of the remaining group, 15 percent were selected at random for follow-up. Further description of this sample has been published previously.[5–7]

In 1985–88, the attempt was made to contact the entire population studied at baseline in 1973. Of the original population, 253 were lost to the study; 219 could not be located; 19 refused; 15 had died. Follow-up data were successfully gathered on 891 subjects, or 78 percent of the original pool.

The sample for the present study (N = 375) includes subjects for whom data are available both from the 1978 study and from the 1985–88 population follow-up. Subjects with very high or very low systolic blood pressure measurements when they were teenagers are overrepresented in this group, as are younger participants. As seen in Table 1, the typical 1985–88 participant was a White, married, full-time employed, high school graduate born in 1958. About half of the study group was male.

At both 1978–79 and 1985–88 data collections, participants were located by searches of local public documents, contacts with relatives and friends of the participants, and by placing classified advertisements in local and regional newspapers. Measurements were usually made at the project office in Bourbon County. For participants not willing to travel to the project office, home visits were performed by project staff throughout the state of Kentucky. For two out-of-state participants, Physical Measurements, Inc was hired to provide home visits at which a blood sample, blood pressure, and other anthropometric measurements were obtained according to protocol. Questionnaires were also completed by these two participants. Blood pressure, anthropometric, and medical history data were collected at both waves. The Type A measure (the Jenkins Activity Survey, Form C)[8] was administered only in 1985–88. Type A behavior was measured with the JAS Type A subscale comprising 21 items from the longer instrument. Each response was assigned a weight and summed according to the method of Jenkins.[8] Blood lipid analyses and other cardiovascular assessments[7] are available on a subset of the participants (N = 98).

Quetelet index[9]: Q = weight in kilograms/(height in meters)^2 was calculated. Blood pressure was measured in the right arm after the subject was seated for at least five minutes.

Some College	83	(22.1)	53	(14.1)
College Diploma	7	(1.9)	48	(12.8)
Race				
White	301	(80.3)		
Black	74	(19.7)		

*375 is the total number of participants. Smaller numbers are due to missing information on some variables.

Three measurements by a trained observer were taken over a 10–15 minute period using a standard mercury manometer and cuff calibrated for arm circumference; these readings were averaged. Blood samples were analyzed for total serum cholesterol and serum triglyceride values by the autoanalyzer method described in the Lipid Research Clinics Manual of Laboratory Operations.[10]

We studied systolic and diastolic blood pressure, serum cholesterol, and serum triglyceride levels, body mass, and smoking behavior as indicators of risk. Change in risk status was measured as the difference in scores from 1978–79 to 1985–88 on each of these variables. Using change scores for each of the risk factors as outcomes, we calculated a three-way factorial model for all risk factors except smoking change, with behavior pattern, race and sex as the explanatory variables. Change in number of cigarettes smoked was treated as a categorical variable for log-linear modeling and contingency table analysis. Race, sex and body mass were included as potential control variables.[12] Relations between behavior pattern and risk variables were affected by race and sex, but not by change in body mass (data available on request) so change in body mass was removed from further analyses.

Results

Coronary risk factor means and standard deviations at the two time periods are shown in Table 2.

The three-way factorial analysis for change in systolic blood pressure revealed that only the main effect of behavior pattern accounted for significant variance in change in systolic blood pressure between 1978–79 and 1985–88 assessments. As shown in Table 3, Type A subjects experienced a mean 2.90 ± 1.29 (standard error) mmHg change, whereas Type B subjects showed a mean −1.47 ± 1.22 mmHg change in systolic blood pressure. The Type A subjects experienced greater increases in systolic blood pressure than Type B subjects in the entire sample ($p = 0.01$), in women ($p = 0.02$) but not in men ($p = 0.23$), and in Blacks ($p = 0.05$) but not in Whites ($p = 0.12$).

TABLE 2—Coronary Risk Factors in Participants, Means and Standard Deviations, Bourbon County, Kentucky, 1978–79 and 1985–88

	N	1978–79	1985–88
		Means SD	Means SD
Systolic Blood Pressure	375[+]	120.27 ± 14.90	120.69 ± 16.07
Diastolic Blood Pressure	375	73.08 ± 11.35	75.28 ± 11.88
Serum Cholesterol	98	167.21 ± 37.32	204.19 ± 43.18
Serum Triglyceride	98	107.53 ± 77.81	168.36 ± 99.65
Body Mass Index	371	24.17 ± 6.48	26.62 ± 5.81
JAS Type A Score	375		211.28 ± 72.82
Cigarettes/Day	369	7.24 ± 10.99	9.18 ± 13.39

[+] Fewer than 375 cases on a variable are due to missing information (except for the serum cholesterol and serum triglyceride variables in which sample design called for fewer cases).

In the three-way factorial analysis for change in diastolic blood pressure, none of the explanatory variables or their interactions were statistically significant, but Type A individuals rose an average 3.80 ± 1.17 mmHg, whereas Type B individuals rose 0.50 ± 1.11 mmHg in diastolic blood pressure (Table 4). The Type A subjects experienced somewhat larger increase in diastolic blood pressure than Type B subjects in each contrast especially among Blacks and women.

Factorial analysis of changes in total serum cholesterol, serum triglyceride, and body mass values showed no statistically significant main or interaction effects on change in any of these three risk variables.

Log-linear modeling analysis was performed with smoking, the outcome, divided into participants who decreased, remained unchanged and increased cigarette consumption from 1978–79 to 1985–88, and with behavior pattern, sex and race the predictors. Only behavior pattern was significantly associated with smoking change. Table 5 shows that Type As increased smoking more than type Bs, and that Type Bs held their smoking at the same level to a greater extent than Type As. Log-linear analysis found that the behavior pattern/smoking change association was statistically significant in Black females but not in the other three race/sex groups.

Discussion

In 1981, an authoritative panel examined the available evidence and judged the Type A behavior pattern to be a risk factor for coronary disease, comparable in impact to smoking, elevated cholesterol, and elevated blood pressure.[4] Subsequent results call that conclusion into question.[13–15] Recent research suggests that underlying hostility is the aspect of Type A behavior that is most strongly predictive of coronary heart disease endpoints.[16] A reanalysis of the Multiple Risk Factor Intervention Trial (MRFIT) data, one of the major recent studies failing to find a Type A/coronary disease association, has found indicators of hostility to significantly predict coronary disease incidence.[17]

Appropriate measurement of Type A behavior is uncertain,[18] but at best is only modestly associated with other coronary risk factors,[19,20] and has been seen as an independent risk factor. This study suggests that, in young adults, Type A behavior pattern is associated with more rapid increases in two well-accepted coronary risk factors. Type A behavior may operate differently at different ages to produce

TABLE 3—Mean Change (± standard error) in Systolic Blood Pressure for Sex/Race/Behavior-Pattern Groups*

	Males		Females		Both Sexes		
	Type A	Type B	Type A	Type B	Type A	Type B	A vs. B (p)
White	1.17 (1.38)	−0.66 (1.65)	1.72 (1.68)	−1.40 (1.58)	1.44 (1.09)	−1.03 (1.14)	0.12
Black	4.93 (3.49)	0.73 (2.88)	3.79 (3.10)	−4.56 (3.19)	4.36 (2.34)	−1.91 (2.15)	0.05
Both Races	3.05 (1.88)	0.04 (1.66)	2.76 (1.76)	−2.98 (1.78)	2.90 (1.29)	−1.47 (1.22)	
A vs B (p-value)	0.23		0.02				0.01

*Three-way analysis of variance found a significant ($p < .05$) main effect for Type A/B behavior pattern but no other main or interaction effects.

TABLE 4—Mean Change (± standard error) in Diastolic Blood Pressure for Sex/Race/Behavior-Pattern Groups*

	Males		Females		Both Sexes		
	Type A	Type B	Type A	Type B	Type A	Type B	A vs. B (p)
White	2.16 (1.26)	1.76 (1.50)	3.08 (1.53)	2.27 (1.44)	2.62 (0.99)	2.02 (1.04)	0.68
Black	4.40 (3.18)	0.00 (2.62)	5.58 (2.82)	−2.00 (2.90)	4.99 (2.13)	−1.00 (1.96)	0.04

A vs B (p-value)	0.29		0.07				0.04

*Three-way analysis of variance found no significant main or interaction effects.

TABLE 5—Contingency Table Analysis (chi-square) of the Association between Behavior Pattern and Change in Smoking Behavior, 1978–79 to 1985–88 (N = 369)

	Behavior Pattern			
	Type B		Type A	
Smoking Change	No.	%	No.	%
Decreased	21	11.8	28	14.7
Stayed Same	121	68.0	107	56.0
Increased	36	20.2	56	29.3
Total	178	100.0	191	100.0

chi-square = 5.76; d.f. = 2; p = 0.056

eventual coronary disease endpoints. In young adulthood, Type A might promote exacerbation of two coronary disease risk factors and thereby support early atherogenesis. In these younger adults, the Type A pattern may reinforce the smoking habit by motivating individuals toward greater cigarette consumption. The Type A pattern may also stimulate more rapid escalation of blood pressure in ways analogous to those demonstrated in stress laboratory research on Type A responsiveness to hostile challenges.[18] Type A behavior may become less strongly associated with these risk factors in middle age as life situations become more predictable and manageable.

Whether a Type A measure taken in 1985–88 reflects status in 1978–9 might be questioned, but Type A measures have been shown to be stable in young adults and in children.[21–23] At the least, these data suggest that those who measure as Type A in their late 20s are more likely to have experienced a steeper increase in blood pressure and smoking during the preceding decade than their Type B counterparts.

In the study of "Framingham offspring,"[3] their lifestyle, and changes in serum cholesterol, lipoproteins and blood pressure, no association was found between Framingham Type A measures (total scale, trait subscale, and job-related subscale) and changes in systolic or diastolic blood pressure, total, high density lipoprotein, low density lipoprotein, very low density lipoprotein cholesterols, and the ratio of total to high density lipoprotein cholesterols. However, in men only, the Framingham Type A trait subscale was independently predictive of the ratio of total to high density lipoprotein cholesterols by regression analysis. This significant finding could not be examined in the present study because of our lack of lipoprotein data. We are also unable to compare our body mass, serum triglyceride, and smoking results to those of the Framingham offspring study as the latter did not report Type A by body mass, serum triglyceride, and smoking associations.

Neither the design nor the data of the present study permits firm explanations for the stronger association of Type A with blood pressure and smoking changes in women and Blacks than in men and Whites. One possible explanation is that Type A women and Blacks, because of social discrimination, find themselves more consistently engaging in the Type A coping responses to challenges.

In summary, this nine-year cohort study uncovered evidence that individuals with the JAS-measured Type A behavior pattern were likely to experience a steeper increase in blood pressure and rate of cigarette smoking during their third decade of life than their Type B counterparts. These results were found in analysis of the whole study group, but appeared stronger in women and Blacks for blood pressure, and in Black women for smoking. In light of earlier findings of no relationships between Type A behavior and coronary disease risk factors, these results suggest that age differences may affect the strength of those associations.

Behavioral Covariates of Waist-to-Hip Ratio in Rancho Bernardo

AMI LAWS, MD, RICHARD B. TERRY, BA, AND ELIZABETH BARRETT-CONNOR, MD

Abstract: We examined lifestyle and dietary habits in 685 men and 943 women (mean age 67 years) who completed an interview, examination, and food frequency questionnaire in 1984–87. Waist-to-hip ratio increased with age and body mass index in both men and women. In multiple regression, waist-to-hip ratio was independently associated with smoking, alcohol consumption, and exercise in men, and with smoking and alcohol consumption in women. The data suggest that waist-to-hip ratio is affected, at least in part, by behavioral, and potentially modifiable, factors. (*Am J Public Health* 1990; 80:1358–1362.)

Introduction

Male pattern abdominal or truncal obesity, as measured by either waist-to-hip girth ratio, or ratio of subscapular to triceps skin-fold, has been implicated in the development of ischemic heart disease,[1–3] stroke,[3,4] diabetes,[5,6] hypertension,[7–9] and all-cause mortality[2] in both men and women. The association is independent of overall adiposity. In fact, in at least one study, those at highest risk for subsequent ischemic heart disease and death were the leanest subjects, with the greatest waist-to-hip girth ratios.[2]

The etiology of abdominal obesity is not clear. Studies by Bouchard[10] have shown that heredity accounts for only 20–25 percent of the variance in waist-to-hip ratio in the general population. Shimokata[11] and we[12] recently reported that cigarette smoking is related to abdominal obesity independently of age and body mass index. However, since smoking is highly correlated with other health behaviors, such as diet, alcohol consumption, and physical activity, it was unclear whether the increased abdominal adiposity seen in smokers is due to smoking per se, or is a consequence of other, associated behaviors.

In this report we have attempted to determine whether other behaviors, specifically alcohol consumption, physical activity, and diet, also contribute to the waist-to-hip ratio in a defined population.

Methods

The population for this study consisted of older adult residents of Rancho Bernardo, a geographically defined community of Caucasian upper middle-class in Southern California. These subjects were first surveyed in 1972–74 as part of the Lipid Research Clinics Prevalence Study. As previously reported,[13] the initial response rate was 82 percent. In 1984–87, 81 percent of surviving men and women participated in a follow-up evaluation by telephone and/or clinic visit. The 76 percent who were seen in clinic form the basis of these analyses.

Smoking and alcohol use were determined by standardized, self-administered questionnaires which asked subjects if they had consumed any alcohol in the past year, the frequency of their consumption, and the specific forms of alcohol consumed in an average week and in the week prior to the survey. Grams of alcohol for the week prior to the survey and for an average week were computed by means of an algorithm.[14] For smoking, participants were asked if they had ever smoked cigarettes, whether they currently smoked, the usual number of cigarettes smoked per day, and number of years smoked. Exercise was assessed by asking participants if they regularly exercised three times per week. Diet was assessed in a subsample of 737 participants with the Harvard-Willett semi-quantitative food frequency questionnaire.[15]

In clinic, a nurse measured height and weight with subjects in light clothing, without shoes. Body mass index (weight in kg/height in m^2) was calculated as an estimate of obesity. Waist and hip girths were measured over light, single thickness clothing with participants standing in an erect position with feet together. Participants were asked to bend forward and return to an erect posture. Waist girth was measured in cms at the bending point. Hip girth was measured in cms at the iliac crest. A 75 gram oral glucose tolerance test was administered in the morning after a requested 12-hour fast; diabetes was defined by World Health Organization (WHO) criteria.[16]

Among the 841 men and 1,117 women ages 50–79 who participated, 125 men and 114 women had non-insulin dependent diabetes by history or glucose tolerance test. Non-insulin dependent diabetes, which is strongly genetically determined,[17] and related to waist-to-hip-ratio was excluded from the present analyses in order to emphasize attributes which could be modified by behavior. Subjects with incomplete diabetes data (N = 84) were likewise excluded. These analyses, therefore, are based on 685 men and 943 women without diabetes. There were no other exclusions for disease, but all subjects were healthy enough to come to the clinic.

Data were analyzed using Statistical Analysis Systems (Cary, NC). Groups were compared using analysis of variance; age and age and body mass index-adjusted values for waist-to-hip ratio were compared by analysis of covariance. Pearson correlation coefficients were used to assess the correlation of waist-to-hip ratio with the dietary variables. Waist-to-hip ratio was sufficiently normally distributed not to require transformation. Multiple linear regression was used to determine the independent contributions of the behavioral variables to waist-to-hip ratio. All probabilities reported are for two-tailed tests.

Results

The mean age of both men and women was 67 years (Table 1). Men were heavier and had a higher waist-to-hip ratio than women. BMI decreased with age in men ($r = -.19$, $p < .001$) but not in women. Waist-to-hip ratio correlated with BMI in both men and women, ($r = .40$; $r = .31$, respectively).

Current	24 (17)	16 (13)
% Drinkers	75	65
Alcohol past week** (mean gms)	142 (126)	102 (92)
Alcohol average week** (mean gms)	152 (123)	111 (88)
% Exercisers	87	80

Values are mean ± SD.
*among smokers
**among drinkers

When adjusted for BMI, waist-to-hip ratio increased with age in both men and women (r = .11, r = .23, respectively).

Almost two-thirds of the men and over one-third of the women had smoked in the past, but only 12 percent of the men and 16 percent of the women were current smokers. Over two-thirds of men and women reported drinking at least one or two drinks per month and most reported regular physical activity. Among users, men smoked more cigarettes and drank more alcohol than women.

Waist-to-hip ratio was higher in men and women who had ever smoked compared to those who had never smoked, and was higher in the upper quartile of drinkers (>9 oz/wk for men; >7 oz/wk for women) compared to all others. Waist-to-hip ratio was lower in men and women who reported regular exercise compared to those who did not (Table 2).

Waist-to-hip ratio, adjusted for age and BMI, was lowest in never smokers, intermediate in former smokers, and highest in current heavy smokers (Figure 1). The magnitude of the difference in waist-to-hip ratio between never smokers and current heavy smokers was as large in the women as in the men, despite the fact that within each category the women smoked fewer cigarettes per day.

Figure 2 shows mean waist-to-hip ratios by five drinking categories based on alcohol consumption in the week prior to the clinic visit week. Similar results (not shown) were found based on alcohol consumption in an average week. In both men and women, the heaviest drinkers had the highest waist-to-hip ratios.

Correlations between a number of dietary variables from the Harvard-Willett food-frequency questionnaire and waist-to-hip ratio were examined in 335 men and 402 women, shown in Table 3. Among the dietary variables, percent calories from alcohol was positively correlated with waist-to-hip ratio in men and women, as was absolute alcohol intake (data not shown). The only other dietary variable significantly correlated with waist-to-hip ratio was percent calories from carbohydrate (exclusive of alcohol) which was inversely correlated with waist-to-hip ratio in men.

Cigarettes per day for former and current smokers, alcohol as a continuous variable, and exercise were entered into a multiple linear regression model with age and BMI. There was no significant interaction of smoking with alcohol intake in the model. As shown in Table 4, in both sexes, age, BMI, alcohol intake, and smoking were independently associated with waist-to-hip ratio. Exercise was independently associated with waist-to-hip ratio in men but not in women. Overall, these attributes explained 21 percent of the variance in waist-to-hip ratio in men and 16 percent in women.

Discussion

The study confirms observations by Shimokata,[11] and extends earlier observations in this population[12] by demonstrating that effects of smoking and drinking on waist-to-hip ratio are independent and additive.

The fact that the increase in waist-to-hip ratio associated with drinking was accounted for by the heaviest drinkers is consistent with one possible mechanism, an increase in adrenal cortisol production which has been reported in alcoholics and has been termed "alcohol-induced pseudo-Cushing's syndrome."[18,19] It is well-known that central obesity is a prominent feature of Cushing's syndrome.[20] Although pseudo-Cushing's is apparently a relatively uncommon complication of alcoholism,[21] it is possible that a lesser degree of abnormality in cortisol secretion associated with heavy drinking could affect waist-to-hip ratio in the absence of clinical Cushing's syndrome.

The association of smoking with increased waist-to-hip ratio in women may be explained by the fact that women smokers have increased levels of adrenal androgens[22,23]

which have been shown to be associated with upper body obesity.[24] Increased cortisol levels in postmenopausal women smokers[23] also may contribute to increased abdominal obesity. In men, smoking is associated with increased adrenal androgens and estrogen, however, there are few data on the association of sex hormones with waist-to-hip ratio in men.[25] One study showed the only difference between men with higher vs lower waist-to-hip ratio was a lower sex hormone binding globulin in the former group.[26] In the data presented here, the association of smoking with waist-to-hip

Women are shown in the lower panel; cutpoints for the quartiles are as follows: I < 1 oz/wk, II 1–3.3 oz/wk, III 3.3–7 oz/wk, IV > 7 oz/wk.)

ratio was stronger in women than men, consistent with an effect of increased adrenal androgens. Adrenal androgens may have a less obvious effect in men, who have high levels of testicular androgens.

Except for alcohol, there appeared to be little relationship between dietary factors and waist-to-hip ratio other than the inverse relationship with carbohydrates in men. This association could be a chance finding, reflecting the multiple diet comparisons. Alternatively, a high carbohydrate diet may be associated with a healthy lifestyle and exercise.

The apparent sex difference in the relationship of exercise to waist-to-hip ratio is compatible with metabolic studies which show different effects of exercise on fat mass in men compared to women.[27] After a physical training program, obese men show a decrease in total body fat, whereas women do not.[28–30] Since waist-to-hip ratio is highly correlated with percent body fat,[31] exercise could have a greater effect on waist-to-hip ratio in men than in women.

These findings are based on older, White men and women, and may not be generalizable to younger sub-

jects or to minorities. However, the age group studied is that in which "middle-aged spread" is classically manifest. The analyses were based on self-reported behaviors, and it is possible that these were inaccurately reported by the participants. Probable validity of the reported alcohol intake is strengthened by concordance with aspartate aminotransferase activity and HDL-cholesterol in this cohort.[32] Likewise, the validity of self-reported exercise in this cohort is strongly suggested by its concordance with pulse and HDL-cholesterol.[33] In any event, misclassification of self-reported behaviors usually serves to obscure an association, not create one.[34]

The fact that waist-to-hip ratio appears to be determined, at least in part, by behavioral factors has implications for intervention. This risk factor for increased morbidity and mortality may be modifiable by interventions aimed at changing the behaviors which affect it. This would be expected to have a favorable impact on general, and specifically, cardiovascular health.

The Framingham Disability Study: Relationship of Various Coronary Heart Disease Manifestations to Disability in Older Persons Living in the Community

JOAN L. PINSKY, MA, ALAN M. JETTE, PT, PHD, LAURENCE G. BRANCH, PHD,
WILLIAM B. KANNEL, MD, MPH, AND MANNING FEINLEIB, MD, DRPH

Abstract: The relation between coronary heart disease and disability was examined in 2,576 community-dwelling women and men ages 55–88 years. These Framingham Study participants were originally recruited in 1948–51 for an examination of cardiovascular disease. Twenty-seven years later, remaining members of the cohort were interviewed to ascertain physical abilities, and a score on a disability scale was assigned. Multivariate logistic analyses examined disability in relation to uncomplicated angina pectoris (AP), complicated AP, and coronary heart disease other than AP, controlling for possible confounders. In younger and older women and men, uncomplicated and complicated AP were associated with disability. Coronary heart disease other than AP was associated with disability only in the younger men. Congestive heart failure predicted disability only in the women. These results suggest that onset of AP should be recognized as a critical point in the development of disability and that AP is a better predictor of disability than is myocardial infarction or coronary insufficiency. (*Am J Public Health* 1990; 80:1363–1368.)

Introduction

Although the coronary heart disease (CHD) mortality rate in the United States has been declining for two decades,[1] CHD remains the leading cause of death.[2] There are indications that CHD morbidity has not been following the same trend as mortality, and that the number of persons, particularly older persons, disabled from CHD remains high. Estimates of the percentage of persons with ischemic heart disease who were disabled by their condition in 1980 range from 36 percent in 55–64 year old women to 76 percent in men 75 years and older.[3] Heart disease ranks as third among the leading chronic conditions causing limitation of activity; in 1983–85, 5.6 million persons were affected* and this number was higher than a 1980 estimate.**

A better understanding of the CHD-disability relationship may provide leads to primary and secondary preventive health care strategies.[4] Some researchers have sought to identify predictors of disability among persons with CHD.[5–7] The Framingham Study enables us to look at disability in a non-institutionalized population of older persons, to compare physical limitations of those with and without CHD, and to learn more about the relationship of disability to specific CHD manifestations. Our specific question is: among a population of non-institutionalized women and men ages 55–88 years in 1976–78, is disability related to uncomplicated angina pectoris (AP), CHD other than AP, and AP complicated by other CHD? Since congestive heart failure is closely associated with CHD, we will also examine its relation to disability.

Methods

Study Sample

Between 1948 and 1951, the Framingham Study assembled a cohort of 5,209 persons, ages 28–62 years in Framingham, Massachusetts.[8] Information on potential cardiovascular disease risk factors and disease manifestations were obtained every two years by interview, physical examination, and laboratory tests. By December 1979, 31 years after the inception of the study, the 15th examination cycle had been completed.

The Framingham Disability Study (FDS) was designed to yield a quantitative assessment of levels of physical and social disability based on respondents' self-reported information. Surviving members of the Framingham Study reported their current level of functioning in interviews from September 1976 (midway through the 14th examination cycle) through November 1978 (midway through the 15th examination cycle). This time period will be referred to throughout this report as examination 14/15. Descriptions of the prevalence findings on physical disability from this study have been reported previously.[9]

When the Framingham Disability Study interviewing began, 1,649 of the original cohort of 5,209 had died, 218 had moved away and dropped out of the study, 151 had refused to return for examination, and 354 had been missing from the study for no known reason for at least five years.

Of the remaining 2,837 individuals, 183 (6 percent) were not included in the sample of FDS participants: 41 were nursing home residents who were unable to come to the clinic and were therefore excluded; 87 had come into the clinic for their 14th examination before the disability interviewing began and had not come in for their 15th examination by the time the disability interviewing ended; 43 refused to be interviewed; 11 came for their physical examination but were missed by the disability interviewer due to scheduling difficulties and were unable to be rescheduled; and one person died before a rescheduled interview was taken, leaving 2,654 remaining. Members of the original cohort who did not

participate in the FDS for all of the above-mentioned reasons other than death (N = 882), when compared with FDS participants on characteristics at entry to the Framingham Study, were more likely to be female, older, have a higher mean systolic blood pressure, and a higher body mass index (Table 1).

Seventy-eight (3 percent) of the 2,654 participants were excluded from present analyses for the following reasons: 76 persons had missing values in one or more of the items used to calculate a score on the disability scale, and two had missing values in one of the risk factor measures used as covariates in the analyses. There remained 1,511 women and 1,065 men available for this investigation. Ages ranged from 55 to 88 years for the women and from 56 to 86 years for the men.

Definition of Variables

Coronary Heart Disease Manifestations and Congestive Heart Failure: Determination of these end points was based on information from biennial examinations, surveillance of hospital discharge records and information obtained from private physicians. A panel of physician investigators reviewed all pertinent information against minimal uniform criteria before final assignment of a diagnosis.[10] Examination 14/15 disease status was determined using diagnoses made at any time from examination 1 through examination 14/15.

Myocardial Infarction was diagnosed on the basis of unequivocal specific electrocardiographic criteria or elevated serum enzyme levels. This classification included both recognized myocardial infarctions (ones in which onset of symptoms led the individual to seek medical attention) and unrecognized myocardial infarctions (ones in which no symptoms occurred prior to an examination by a physician).

Angina Pectoris: Brief recurrent chest discomfort of up to 15 minutes duration precipitated by exertion or emotion and relieved by rest or nitroglycerin was regarded as angina pectoris (AP) if two physicians interviewing the participant agreed that AP was definitely present. Electrocardiographic abnormalities were not taken into account in making the diagnosis of AP.

Coronary Insufficiency was diagnosed when a history of ischemic chest pain lasting one hour or more was associated with transient ischemic electrocardiographic criteria.

Congestive Heart Failure: A definite diagnosis of congestive heart disease required a minimum of two major criteria (e.g. increased heart size and rales) or one major and two minor criteria (e.g., rales, bilateral ankle edema, and night cough).

TABLE 1—Selected Characteristics of Original Framingham Cohort Members by Participation in the Framingham Disability Study

	Participation Status		
Characteristics at Entry	No*	Yes	95% CI of difference
Number of persons	882	2,654	
Percent female	65.3	58.9	2.72, 10.03
Age (years)	44.0	40.9	2.49, 3.65
Systolic blood pressure (mmHg)	135.2	131.2	2.55, 5.50
Body mass index (kg/m^2)†	25.7	25.4	0.02, 0.64
Cigarettes per day‡	9.2	8.4	−0.02, 1.72

*Persons who died prior to the start of the Framingham Disability Study were excluded from this group.

Number of observations with missing values: † = 4; ‡ = 19.

The following mutually exclusive subgroups of CHD were considered: uncomplicated AP (AP unaccompanied by coronary insufficiency or myocardial infarction); CHD other than AP (coronary insufficiency or myocardial infarction); and complicated AP (AP accompanied by coronary insufficiency, myocardial infarction, or both).

Disability Scale: The measure of disability used was based on three questions drawn from the Rosow and Breslau Functional Health scale:[11] "Are you able to do heavy work around the house, like shoveling snow or washing windows, walls, or floors, without help?" "Are you able to walk up and down stairs to the second floor without help?" and "Are you able to walk half a mile without help? That's about 8 ordinary blocks." The scale ranged from 0 to 3, reflecting the number of activities which the respondent could not do without help. In other words, the higher the score, the more areas of disability were reported; a score of 0 indicated no disability.

Control Variables: To minimize the chance of detecting a spurious relation between the onset of CHD and subsequent disability, we controlled for the effects of co-existing conditions: other cardiovascular diseases, cardiovascular risk factors, and reported health history of other diseases related to disability. Presence of cardiovascular diseases other than CHD, namely stroke and intermittent claudication, were determined in a manner identical to that used to identify CHD and congestive heart failure, by a panel of physicians using uniform criteria after each biennial examination. Detailed descriptions of clinical criteria employed for the diagnoses of these diseases are available elsewhere.[10]

Cardiovascular Disease Risk Factors: We controlled for the long-term presence of hypertension (coded as a categorical variable taking into account anti-hypertensive drug use as well as blood pressure levels), body mass index (weight, kg, divided by height, m^2), cigarette smoking, and blood sugar, the four cardiovascular disease risk factors found in preliminary analysis to be related to the disability scale. For an explanation of how these risk factor measures were calculated, see Pinsky, *et al.*[12]

Other Health Problems: Several open-ended questions solicited information on participants' lifetime health status. Participants were asked first to mention all of the serious health problems they had had over the years, and were told to include "things that were serious at the time, things that remain as potential problems, or things that in any way limit activities at the present time." A two-part question followed: respondents were asked to mention things they used to do that the cannot do now or had to stop or cut down on; and they were asked what health problem caused each limitation. A maximum of 11 self-reported health problems for each individual were noted during the interview and subsequently classified into one of 233 codes. For the present analyses, 131 codes were grouped into 16 categories of health problems. Age-adjusted analyses indicated that six of the 16 categories were related significantly to the disability scale and are included as control variables in these analyses: amputations, arthritis, back problems, gastrointestinal problems, neurological problems (excluding stroke), and respiratory problems. The categories of health problems which were not related to the disability scale were allergies, cancer, ear problems (including hearing impairment), eye problems (including visual impairment), kidney problems, liver problems, hernias, bone injuries and other accidents, and bone problems other than accidents (data available on request to author).

Statistical Analysis

We chose a logistic model for multivariate analysis which is similar to that described by McCullagh, since the disability scale, our dependent variable, is an ordered categorical variable consisting of four levels of increasing severity. In this approach, the probability of being at the ith level or higher is written as a logistic function of the explanatory variables with a indicator term depending on the value of i. A modification of McCullagh's analysis permits inclusion of continuous explanatory variables. Maximum likelihood was used for estimation, and odds ratios were calculated as the exponent of the appropriate logistic regression coefficient. This model assumes that the underlying odds ratios for the three ordered comparisons of scores on the dependent variable (1 versus 0, 2 versus 1, and 3 versus 2) are equal. We used the logistic procedure in the Statistical Analysis System available from the SAS Institute.[14]

In a previous report, a different disability scale and disease were analyzed separately for women and men, controlling for age.[15] In this report, separate analyses were conducted for two age categories among women and men in an effort to provide additional insights. Furthermore, the lack of a linear relationship between disability and age[9] suggests the relevance of conducting age-specific analyses, rather than putting age in the multivariate model. Each regression included the following control variables: cardiovascular risk factors (i.e. hypertension, cigarette smoking, body mass index, and blood sugar); intermittent claudication and stroke; and six other health problems, (i.e. amputations, arthritis, back problems, gastrointestinal problems, neurological problems, and respiratory problems).

Results

Mean age was 68.3 years for 1,511 women and 67.2 years for 1,065 men. The percentage distribution of scores, from 0 to 3, on the disability scale were, respectively, 61.0, 26.6, 8.2, and 4.2 for women and 78.1, 16.6, 3.6, and 1.7 for men. Not only did a greater percentage of women report disabilities compared to men, but they reported being disabled in more activities than men.

Table 2 displays the age- and gender-specific prevalence of scores greater than 0 on the disability scale by CHD and congestive heart failure status. In all gender and age strata, disability was more prevalent in persons with CHD or congestive heart failure than in persons free of CHD or congestive heart failure. Persons with AP were more likely to be disabled than those with CHD manifestations other than AP. Congestive heart failure was more disabling in women than men.

Gender- and age-specific multivariate logistic analyses examined the relationship between the disability scale and the three CHD manifestations and congestive heart failure. Using the results of these analyses, odds ratios were calculated, representing a comparison of the disability status of persons with the manifestation to persons free of all disease categories included in the model (Table 3). An odds ratio of one means that those with the manifestation have the same chance of having a higher score on the disability scale as persons free of all disease categories included in the model, within each particular gender and age subgroup. For both women and men, AP both uncomplicated and complicated is strongly related to the disability scale in both age groups, although the relationship weakens with age. CHD other than AP is related to the disability scale only in the younger men. Congestive heart failure is related to disability only in the younger women.

Table 4 presents the results of analyses similar to those in Table 3, except the model also includes terms for other cardiovascular diseases, cardiovascular risk factors, and the self-reports of non-cardiovascular health conditions. The inclusion of these additional covariates did little to affect the results of the analyses. When comparing Table 4 to Table 3, one notes only minor shifts, most of which are downward, in the magnitude of the relationships between disability and disease.

Myocardial infarction is often the event of interest in epidemiological studies and is a much more frequent diagnosis when compared to coronary insufficiency. If we exclude from our pool of persons under study the 56 with coronary insufficiency, our CHD categories become uncomplicated AP, uncomplicated myocardial infarction, and AP complicated by myocardial infarction. Analyses based on these definitions resulted in findings similar to those which included coronary insufficiency. When the three levels of disability were combined, making the dependent variable dichotomous, the pattern of significant relationships did not change at all. For most associations, the strength of the relationship was greater when compared to the analyses using the multichotomous measure.

Discussion

Although our results indicate that AP is a better predictor of disability than other CHD, we were unable to control

for selection factors which could play a role in this study, factors somewhat parallel to the healthy worker effect. Participants are very possibly as a whole healthier in general than nonparticipants. As the longitudinal study progresses, widowhood, geographical relocation, and entrance into institutionalized care facilities probably account for differences in the health status of participants and nonparticipants. For example, one can surmise that the older male participants with congestive heart failure have less severe cases than the surviving cohort members who did not appear for examination 14/15; the milder nature of their disease may partially account for the lack of a relationship with disability.

The loss of severe cases through mortality is probably more relevant among the older persons. The loss of participants results in a smaller population and therefore a possible power problem in our analyses of the 70–88 year olds. It is also important to consider that as age increases, disability due to other conditions for which we have not controlled for such as depression or senility, may interfere increasingly with the assessment of CHD-related disability. Another limitation of our analyses is the absence of consideration of psychosocial variables which may influence physical functioning and consequently could confound our results.

In spite of factors which could attenuate the associations between CHD and disability, suffering from AP was a predictor of disability in each gender and age subgroup. This finding provides epidemiological support for what is commonly observed in clinical practice: once a person develops AP, it chronically affects physical function, regardless of the presence of CHD risk factors, stroke, intermittent claudication, and self-reported health conditions other than cardiovascular disease. Complicated AP was a stronger predictor of disability than uncomplicated AP. This may be explained in part by the differing severity of AP in those with and without other CHD and in part because of limited myocardial reserve imposed by myocardial infarction. That these relationships were generally stronger in men than women could reflect the fact that men suffer more severe disease than women, or that men may initially be more active, enabling their disease to have a greater potential for being more limiting.

The Framingham Study protocol dictated that once an individual was diagnosed as having AP, the individual was never re-evaluated for presence of AP. This limitation prohibited us from identifying those persons who were suffering from AP at examination 14/15; our classification of AP was essentially AP at any time from examination 1 through examination 14/15. We suspect that had we been able to use a determination of current AP sufferers, the relationship to disability would have been even stronger than our analyses indicated.

In sharp contrast to the strongly positive relationship between AP and disability, CHD other than AP was a significant predictor of disability only in the younger men. The finding is consistent with the explanations mentioned above for comparisons between older and younger participants, and between women and men. In these 40 women and 73 men diagnosed as having CHD other than AP, the mean amount of time that elapsed from the most recent event to the time of the disability measurement was greater for the older groups. This fact further helps to explain why the relation between disease and disability are weaker in the older groups; our data seem to indicate that initial disability with acute manifestations probably lessens or disappears with time. This interpretation is consistent with the results of a study of 9,385 men and women aged 18–103 years.[16] In this study a physical functioning measure, based on self-reported capacity to perform a variety of physical activities, was significantly related to a multivariate model to occurrence of myocardial infarction within the prior 12 months. Angina was also found to be significantly related to physical functioning.

The ostensibly puzzling difference between men and women in their congestive heart failure-disability relationships (significant in women but not in men) may be understood better when the relationships between CHD and congestive heart failure are examined. Among the men, 85.7 percent of those with congestive heart failure also had CHD, whereas only 47.5 percent of the women with congestive heart failure were diagnosed as also having CHD. One could hypothesize that in the 21 men with congestive heart failure, their CHD was so disabling that additional disability could not be detected. Furthermore, the very low congestive heart failure prevalence in the men probably works against the detection of a relation with disability.

While we found only one other study comparing disability in persons with and without CHD,[16] other studies have examined predictors of cardiac disability in patient-based populations, the results of which are largely complementary to ours. In a study of men ages 35–77 years with CHD, an activity score was calculated from a self-administered instrument and included such items as sports, walking, sex, and heavy housework; regression analysis on 98 of these men showed that angina was related to total activity score, but past myocardial infarction history was not so related.[6] Chirikos and Nickel studied 976 men and women (age range not identified) who were hospitalized for acute coronary attacks and found in their multivariate analyses that presence of cardiac and chronic diseases, including angina, was significantly related to restoration of functional capacity as determined by telephone interview at 6, 18 and 24 months post-hospitalization.[7] They also noted that gender was not significantly related to the restoration of functional capacity. Results from Hlatky, *et al*, are very different; in their study, a self-administered questionnaire was used to determine whether the study participants were not working because of disability.[5] Among 814 men younger than 60 years with coronary artery disease, an anginal pain scale was not related to work disability, but history of myocardial infarction was so related. This study utilized a very different type of disability measure, which might partially explain why its results differ from ours and above-mentioned studies.

In addition to the selectivity factor previously noted, another limitation of the study design warrants mention. Our study question assumes that disability developed subsequent to disease. Because assessment of physical disability status was made at a single point in time (examination 14/15), it is possible that some persons were disabled at the start of their participation in the Framingham Study or otherwise preceded the diagnosis of CHD. The items comprising the disability scale have been asked at a later Framingham examination; analyses which include these data will hopefully enable a study of change of disease status with change in disability status.

In conclusion, our analyses revealed a striking difference in the disabling effects of AP and other CHD. AP, whether complicated or not, was predictive of disability, whereas other CHD was not, except in the youngest women. This finding is in contrast to the relative roles of CHD manifestations when the outcomes of interest are further morbidity and mortality; that is, AP is less predictive of CHD morbidity and mortality than other CHD.[17] The interactions between disability and disease are complex, and it is important to keep in mind that the presence of disease may not necessarily contribute to disability, further morbidity, and mortality to a similar extent. Finally, age is another important factor to take into consideration, as our analyses indicated differences in the strength of the relationship of disability to CHD in different age groups.

These results further the cause of preventive cardiology. Our findings provide population-based evidence to back up clinical knowledge of consequences of CHD. Motivation for control of cardiovascular risk factors is not only the avoidance of well-documented morbidity and mortality from CHD other than angina pectoris; our study demonstrates clearly and provides quantification of the disabling nature of angina pectoris.

The Effects of Psychosocial Work Organization on Patterns of Cigarette Smoking among Male Chemical Plant Employees

KATHRYN L. GREEN, SCD, AND JEFFREY V. JOHNSON, PHD

Abstract: We tested the hypothesis that job strain (the combination of high psychological job demands and low work control) is positively associated with smoking prevalence and intensity in a study group of 389 males employed in a chemical plant, using a self-administered questionnaire. In a logistic regression analysis which controlled for a number of sociodemographic factors, job strain was not found to be associated with smoking cessation. However, among smokers, those in higher-strain jobs smoked more heavily than those in lower-strain positions (OR 1.70, 95% CI = 1.10, 2.61) and were more likely to have increased the amount they smoke (OR 3.72, 95% CI = 1.92, 7.17). (*Am J Public Health* 1990; 80:1368–1371.)

Introduction

Cigarette smoking is a harmful habit, not only in terms of its health consequences but also with respect to its financial impact. Workers who smoke are said to have higher rates of absenteeism, hospitalization, illness, and job-related accidents; each employee who smokes is estimated to cost business $300 to $1000 a year.[1] Corporate concern about such facts is indicated by the current proliferation of worksite anti-smoking policies and cessation programs. However, in contrast to the extensive documentation of smoking's effects on employment, the converse of this relationship—how work may influence smoking behavior—remains largely ignored.

Overall, blue-collar workers are much more likely to smoke and less likely to quit smoking.[2] The differential is somewhat smaller for women than for men. While the proportion of persons who have made a serious attempt to quit does not differ substantially between white- and blue-collar workers (64 vs 59 percent, respectively), white-collar workers are more likely to have succeeded (48 vs 35 percent success).[3]

The relation between occupation and smoking may be mediated by the psychosocial work environment. Despite a lack of consistency in definitions and measurement, research has generally found work-related stress to inhibit cessation[4,5] and increase intensity of smoking.[4-7] Workplace social support may affect smoking behavior negatively or positively, depending on the prevalence of smoking and attitudes towards quitting among co-workers.[4,8] In addition, studies of work socialization have indicated that low job control contributes to psychological characteristics such as poor self-esteem and external locus of control,[9,10] which have been associated with a lower likelihood of quitting smoking.[11,12]

Karasek and his colleagues have defined job strain as the combination of high psychological demands with low decision-latitude or control.[13] Research in Sweden and the United States using this model has found high-strain work—where job demands are high and there is little opportunity for control—to be associated with an increased risk of cardiovascular disease (CVD), independent of smoking.[13-18] More recently, a modified version of this formulation which includes social support has identified a high CVD risk group of strained and socially isolated workers.[19,20] If job stress or strain also increases smoking, it would pose a double risk to cardiovascular health: directly, through physiological mechanisms, and indirectly, through behavioral risk factors such as smoking.

The central hypothesis of the present study was that job strain, defined as a high ratio of psychological demands to control, is negatively associated with smoking cessation and positively associated with both smoking intensity and an increase in smoking over time. A secondary objective was to explore the relationship between workplace social support and smoking behavior.

Methods

Study Group

The population surveyed consisted of the approximately 800 employees at a chemical manufacturing plant in the northeastern United States. Two years prior to the study, the plant had established an on-site "Wellness Center," consisting of exercise facilities staffed by two health educators.

Each employee was mailed a copy of the questionnaire described below; after two mailed follow-ups to non-respondents, a final response rate of 60 percent among full-time employees was obtained. From the 466 completed questionnaires, 23 females and 54 males under the age of 40 were excluded, since their work histories were substantially different from those of the majority of the workforce and their numbers too small to allow for meaningful subanalysis. Thus, all analyses were conducted on a study group of 389 male respondents ages 40 and above. The typical study group member was White (93 percent), married (85 percent), and had a high school (51 percent) or more than high school (29 percent) education. Over half of respondents reported earning between $30,000 and $40,000 annually.

Non-respondents were less likely than respondents to have registered with the exercise center (28 percent vs 39 percent), and less likely to be salaried (22 percent vs 34 percent) (as opposed to being paid hourly).

Table 1 presents the distribution of job titles in the study group, classified in seven occupational categories. Almost three-fourths were paid on an hourly basis. Half of the group, mostly hourly employees, worked shifts. The average length of time with the company was just over 25 years.

Questionnaire

The questionnaire collected information on job characteristics, health behavior, and demographics.

Business managers, lesser professionals	18	(4.7)
Higher executives, major professionals	12	(3.1)
No answer	4	
Total	389	

Job Characteristics: This section was based on Karasek's Job Content Instrument (JCI),* with minor modifications. The JCI was designed to measure the content of work tasks in a way which is applicable to all jobs in the United States. Its main focus is the psychological and social structure of work. The six job characteristic scales formed from this questionnaire assess 1) job control, 2) psychological demands, 3) physical demands, 4) job insecurity, and 5–6) social support from co-workers and from supervisors. In addition, a seventh variable measuring job strain was created by dividing the standardized score on the psychological demands scale by the standardized control score. In accord with the job strain hypothesis, the higher the demand/control ratio, the higher the level of strain. (Details of scale content and construction are in the Appendix.)

Smoking Behavior: From the questions on smoking behavior, three dichotomous smoking variables were created.

1) Smoking cessation (smokers vs ex-smokers);

2) Smoking intensity (less vs more than a pack a day);

3) Change in smoking habits since starting to work for the company (started smoking or increased amount vs no change or decreased).

Statistical Analysis

For the bivariate analyses, simple odds ratios (ORs) measured the strength of the associations, with corresponding 95 percent confidence intervals (95% CIs) calculated using Woolf's method.[21]

Multivariate analysis of the relations between job characteristics, demographic factors, and smoking behavior was conducted. In a logistic regression analysis, a stepwise backward selection procedure was used to determine which of the job characteristics and/or demographic variables were predictors of each smoking behavior variable with the inclusion level set at 0.10.

Standardized ORs (SORs) with 95 percent confidence intervals were computed from the standardized logistic coefficients, following the method proposed by Rosenmann, *et al.*[22] To indicate a negative association, a [−] sign is used, rather than the reciprocal of the SOR. The following variables were initially entered into the logistic model: job strain (demand/control ratio), job insecurity, physical demands, co-worker support, supervisor support, shiftwork (1 = work shifts; 0 = do not), marital status (1 = divorced, 0 = other), education, income, age, and race (1 = White, 0 = other).

To further examine the relation between job characteristics and behavior, multiple contingency tables were formed by stratifying the data into categories of each of the other variables retained in the logistic model, alone and in combination. From these tables, an estimate of a uniform OR over all strata was calculated using Mantel-Haenszel procedures.[23] The heterogeneity of the ORs across strata was determined by a likelihood ratio test of heterogeneity.[24] Confidence intervals around the Mantel-Haenszel point estimates were then calculated using Miettinen's test-based interval estimation procedure.[25] This analysis produced generally similar results to logistic regression, with all ORs heterogeneous across strata; thus, multiple contingency tables are discussed here only where the stratum-specific ORs are of interest.

Results

Almost half (49 percent) of the 389 study participants had quit smoking and 31 percent were current smokers. Half of the former smokers (50 percent) had quit 11 or more years earlier; just over one-third (36 percent) had quit between two and 10 years earlier and 14 percent had quit within the preceding year.

Almost half of the 117 smokers (46 percent) reported smoking more than 20 cigarettes per day; a slightly smaller proportion (41 percent) smoked 10 to 20 a day, and 13 percent smoked fewer than 10. In response to the question of whether their smoking habits had changed since starting to work for this company, 52 percent reported no change, 35 percent an increase, 10 percent a decrease, and 3 percent said they had only begun to smoke since starting to work.

Bivariate Analyses

Bivariate analyses found that, as predicted, smokers in high-strain jobs are much more likely to smoke heavily and to report an increase in smoking since starting to work for the company; those in low-strain jobs are also more likely to have quit smoking, although this association is weaker (Table 2).

There is a steady increase in the proportion of heavy smokers as job strain increases. Similarly, the proportion of smokers reporting an increase in smoking grows progressively with increasing job strain. Furthermore, the proportion of smokers who have decreased or maintained their smoking is inversely related to job strain, with a significant number reporting a decrease in smoking only at the lowest level of strain.

Multivariate Analyses

Controlling for demographic and other job characteristic variables through logistic regression reduces the association between strain and cessation (Table 3), but the relations between job strain and intensity of smoking and between job strain and increase in smoking remain strong (Tables 4 and 5). In each case, adjusting for the demographic variables remain-

TABLE 2—Bivariate Relations between Smoking Behavior Variables and Job Strain (Low vs High)

Smoking Behavior Variables	Odds Ratio (95% CI)
Cessation (former vs current smokers)	1.71 (0.92, 3.17)
Intensity (≤20 cigarettes per day vs >20)	3.86 (1.35, 10.99)
Change in smoking habits (increased/started vs no change/decreased)	7.78 (2.28, 26.50)

Job Strain	3.72 (1.92,7.17)
Age	−2.16 (−1.32, −3.53)
Education	−2.09 (−1.22, −3.55)
Income	1.70 (1.00,2.89)

ing in the model strengthens the association between job strain and smoking behavior.

The interrelations between smoking cessation, co-worker support, and demographic variables were examined further in multiple contingency table analysis. Overall, co-worker support is negatively associated with having quit smoking. Adjusting the relation between co-worker support and quitting for both education and age reveals some interesting interactions. Co-worker support has little impact on quitting among younger men, regardless of education. Among older men with a high school education or less, co-worker support is associated with smoking (OR 3.13, 95% CI = 1.33, 6.91), while for older men with more education, it is unstably associated with quitting (OR 4.40, 95% CI = 0.82, 20.37).

Discussion

Our failure to find a relation between job strain and quitting may have been due to the cross-sectional nature of the study: half of the ex-smokers had quit more than 10 years earlier and one-fourth 20 or more years earlier, at which time their job characteristics might have been quite different. Another factor which could affect this association is awareness of occupational exposure to carcinogens. In the 1960s and '70s, a number of workers at this plant had developed lung cancer as a result of their in-plant exposure. Most of the older production workers were at the plant during that time and may have been motivated to quit smoking by the deaths of their co-workers.

As hypothesized, smokers who experience an excess of psychological demands relative to control tend to smoke more heavily and are more likely to report an increase in smoking over time than those in jobs where demands and control are better balanced. The question on which the association between job strain and increase in smoking is based relied on self-reported assessment of change over a long period of time. Smokers had worked for the company from nine to 42 years, half between 21 and 29 years. However, the accuracy of the report is suggested by the fact that those who reported an increase in smoking were much more likely to smoke over a pack a day (OR 2.81, 95% CI = 1.24, 5.97).

The most important occupational predictor of smoking cessation in this group was co-worker support. While the overall relation is not strong, the stratified analysis by age and education indicates statistical interactions. For older smokers with a high school education or less, strong co-worker support was associated with a lower likelihood of having quit smoking. For those with more education, the opposite is true: those with strong social support were *more* likely to have quit.

The finding that the effect of social support depends on educational level is consistent with the fact that in this study group, smoking was more prevalent among less-educated older men than among those with more education (31 vs 9 percent current smokers, respectively) and that the former were more likely to report that most of the people with whom they spend time do not care whether they smoke, while the latter tended to believe that most people would like them to quit. Other studies also suggest that higher education is associated with more negative attitudes toward smoking.[26] However, a plausible alternative explanation for this finding is that smoking status affects co-worker support: those who work with a group of smokers may fit in better if they also smoke, while being one of a minority of smokers could impair relations with non-smoking co-workers.

If job strain does increase the intensity of smoking, attempts to encourage smokers in high-strain jobs to quit smoking may be hampered by the nature of their work. Thus, modifying job structure so as to increase control and thereby decrease strain could enhance the success of cessation efforts in this population. This recommendation may seem unnecessary and inappropriate if smoking is simply considered a personal behavior controlled by the individual. However, as Syme has pointed out, the systematic patterning of smoking rates in society strongly suggests that social and cultural forces play an important role in this behavior.[26]

APPENDIX

Construction of Job Characteristic Scales

Control

This scale sums responses to 15 items: six items measure skill discretion (degree to which the job involves learning new things, repetitiveness, creativity, varied tasks, and development of the individual's special abilities), seven items measure decision authority (individual's ability to make decisions about his/her own job, to influence the work group, and to influence company policy), and two items measure closeness of supervision (alpha = .85).

Psychological Demands

This scale sums responses to 10 items assessing how fast and how hard the respondent has to work, hectic nature of the job, whether there is enough time to get the job done, frequency of work under time pressure, amount of work and level of concentration required, presence of conflicting demands, and how often tasks are interrupted or work is slowed down by waiting for other people or departments (alpha = .78).

Job Insecurity

This scale sums responses to six items: level of job security, prospects for career development and promotion, future value of skills, possibility of lay-off in recent past and near future, and ability to keep up with work (alpha = .69).

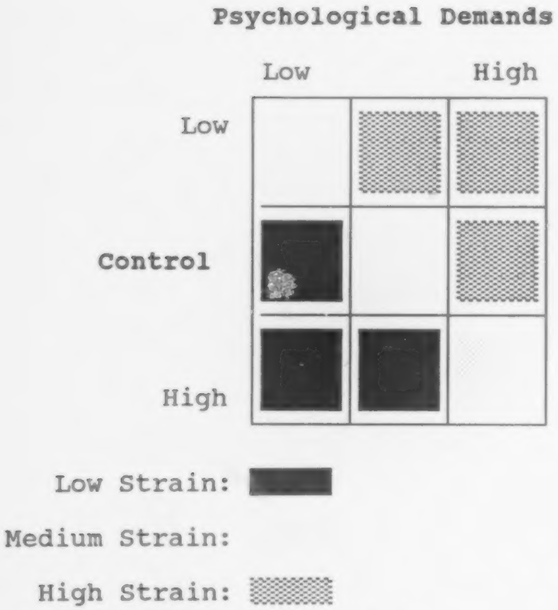

FIGURE 1A—Construction of Three-Level Strain Variable

Physical Demands

This scale sums responses to five items measuring physical exertion (degree to which job involves fast and continuous physical activity, intensive physical effort, and lifting) and ergonomic strain (how often body or head and arms must be held in awkward position) (alpha = .91).

Co-worker Social Support

This scale sums responses to four items measuring co-workers' competence, helpfulness in getting the job done, friendliness, and degree to which they take a personal interest in the respondent (alpha = .71).

Supervisor Social Support

This scale sums five items measuring the supervisor's concern for subordinates' welfare, competence, helpfulness in getting the job done, hostility, and degree to which he/she pays attention to what respondent says (alpha = .84).

Each of these scales was standardized by subtracting the mean from the raw score and dividing the result by the standard deviation; a constant was then added to avoid negative scores. To form contingency tables for bivariate and multivariate analyses, these standardized scores were divided into approximate tertiles (except for the two social support variables which could only be divided roughly at the median, because of their distribution).

Job Strain

In addition to the continuous job strain measure (demand/control ratio), a three-level ordinal form was created from a nine-cell matrix constructed from the three levels of control and psychological demands. Each of these nine cells was then classified into one of three levels of strain, based on the Demand-Control Model, which hypothesizes a dimension of strain running diagonally from the lowest level of demands and highest level of control to the opposite extreme (Figure 1A).

ACKNOWLEDGMENTS

The authors wish to thank the workers and management at the plant at which the study was conducted, and in particular the staff of the Wellness Center for their support and cooperation. This research was supported in part by the National Health Research and Development Program, Health and Welfare Canada, through a National Health Fellowship to Kathryn Green.

This work was presented at the 116th Annual Meeting of the American Public Health Association, in Boston, Massachusetts, November 13–17, 1988.

Use of Fat-Modified Food Products to Change Dietary Fat Intake of Young People

R. Curtis Ellison, MD, Robert J. Goldberg, PhD, Jelia C. Witschi, MS, RD, Ann L. Capper, RD, Elaine M. Puleo, PhD, and Fredrick J. Stare, MD, PhD

Abstract: Food purchasing and preparation practices were modified in two boarding high schools to increase the polyunsaturated-to-saturated fat ratio (P/S) of the diet of students by changing food products rather than attempting to change eating behaviors. During years when fat-modified products were served, the P/S of males increased by 75 percent, versus a decrease of 6 percent during control years. For females, P/S increased by 53 percent during intervention years, versus an increase of 6 percent during control years. (*Am J Public Health* 1990; 80:1374–1376.)

Introduction

In an effort primarily to decrease the risk of premature cardiovascular disease, many health promotion organizations currently advise that all Americans, including young people, modify the amount and type of fat in their diets.[1-3] However, the traditional, one-on-one counseling approach to changing eating behaviors is difficult and time-consuming and is an inefficient method for changing the dietary practices of an entire population. An alternate approach is to change the fat content of food products. This would appear to be particularly relevant today, since such a large proportion of foods consumed in the United States are manufactured, processed, or prepared by the industry, rather than prepared from scratch in the home. This limits the control that individuals have over the amount and type of fat that is contained in the foods they consume.

Studies were carried out at two boarding high schools in New England to determine the impact of modifying fats in food products served in the schools' dining halls on the polyunsaturated-to-saturated fat ratio (P/S) of the diets of students. The goal was to determine the effects on the total intake of nutrients of a "passive" intervention, i.e. an intervention at the level of food production and preparation only. Foods with a higher P/S ratio were purchased and changes were made in food preparation practices in the schools' kitchens, but students were not advised to modify their eating behaviors. This paper reports the effects on students' overall dietary fat intake when the fat-modified products were introduced into the dining halls of each of the two schools over a school year.

Methods

The project was carried out at Phillips Exeter Academy in Exeter, New Hampshire and Phillips Academy in Andover, Massachusetts during 1986–88. School food service workers at each institution were trained to procure and prepare food products in which some of the saturated fat content was replaced by polyunsaturated fat.[4,5] It was sought to avoid alteration of the total fat content of food products. The general intent was to make only those modifications that were feasible in terms of product availability, acceptability, and cost, at the time of the study, for an institutional food service operation.

The study design was that of a longitudinal investigation with food product modification being carried out in each of two schools in alternate school years. After the first month of each school year, modifications of food purchasing and preparation practices were carried out in the school which was serving as the intervention school for the year, while the other school continued to serve usual food products. Some modification was carried out for almost two-thirds of fat-containing foods served. While students were aware that some foods were being prepared using different types of fat, they were not told and, in general, could not tell which items had been modified.

For each of the two years, all students at both schools who were taking selected courses in biology or chemistry (approximately 200 at each school each year) were trained and asked to furnish food diaries at specified times during the year to monitor the effects of the food service changes on their intakes of calories and specific nutrients. All foods ingested were recorded, including those foods that were obtained outside of the dining halls (which furnished 28 percent of calories).[6] Comparisons were made between trends in fat intake in the two schools between a baseline period in the fall (when both schools were serving usual products) and a follow-up period in the spring, when the intervention school students were being served fat-modified products. Analysis of food diaries was performed by trained registered dietitians using the "Food Finder" program at the Center for Clinical Computing, Beth Israel Hospital, Boston, MA.[7]

A total of 6,436 food diaries were submitted during the control and intervention years at the two academies. Data provided by all students completing food diaries during a period were used to calculate mean values for that period.

Results

Baseline and follow-up dietary data for males and females are given in Tables 1 and 2, respectively. At baseline, all groups were consuming approximately 35 percent of their calories from fat. During intervention years, the P/S ratio of the students' diet increased by 75 percent (from 0.53 to 0.93) for males and by 53 percent (from 0.64 to 0.98) for females. During control years, the P/S ratio decreased by 6 percent for males and increased by 6 percent for females.

Discussion

The present study was designed to test the feasibility of changing the P/S ratio of the diet of boarding school students

by modifying the foods served rather than by changing student eating behaviors. The modified products were very well accepted by students. While the estimated effect of the intervention on the diets of students is based on their self-reports of intake, the students had not been told to change their dietary habits or fat intake and thus were unlikely to be trying to please the investigators by reporting what was believed to be desired. Also, in general, they did not know which products had been modified. The study demonstrated that the modification of approximately two-thirds of the fat-containing food products served in the schools' dining halls reduced total saturated fat intake by over 20 percent and resulted in a P/S ratio approaching 1.0, the level currently recommended by most health agencies.[1-3]

The approaches tested in this study are commercially feasible and could be implemented in schools or other institutional food service operations elsewhere. Furthermore, the approaches are applicable to food manufacturers and processors in general. The development of margarines with higher P/S ratios and the replacement of highly saturated coconut, palm, or palm kernel oils with less saturated oils in many food products are examples of such applications. The widespread adoption of such approaches by the food industry could result in healthier foods for Americans.

ACKNOWLEDGMENTS

The authors acknowledge the valuable and tireless input to the study made by Donald Doane, Thomas Pool, Walter Griffin, and other members of the Food Service Departments at the academies. They particularly wish to thank Thomas Hamilton, James Ekstrom, Dr. John Tuthill, and other members of the faculty and staff for their support of the study; Priscilla Harris, Nancy Brown, and Deborah Sullivan for coordinating the study; and especially the students at Phillips Exeter Academy and Phillips Academy, Andover for their cooperation in this project. The authors also appreciate the assistance of the following companies for developing and/or furnishing modified products: Procter & Gamble Co; Kraft, Inc; Oscar Mayer Foods Corporation; Schlotterbeck and Foss; and Waltham Beef Company. Much of the pilot work for this project was supported by the Harvard Human Nutrition Program. The study was supported by grant HL 32821 from the National Heart, Lung, and Blood Institute.

Weekly Food Servings and Participation in Social Programs among Low Income Families

Douglas L. Taren, PhD, Warren Clark, DMin, MDiv, Mary Chernesky, MS, CHE, and Elisabeth Quirk, MEd

Abstract: Low income families were interviewed to determine factors related to the number of family food servings per week. A multiple regression model indicated that participation in WIC (supplemental food program for women, infants and children), household size, and number of different income sources were associated with more family food servings per week. Number of food servings per week decreased the last week of the month most often in families with younger members. (*Am J Public Health* 1990; 80:1376–1378.)

Introduction

Several studies suggest that family food shortages have increased during the past decade. Populations in the United States that are at risk for these shortages include the elderly, single parent families, and children.[1–10] Other studies have shown that participants of government assistance programs also endure food shortages.[11–16] These food shortages follow monthly cycles with the greatest prevalence occurring the last week of the month.[12]

The purpose of this study was to determine if the number of food servings per week could be used to assess food shortages that occur at the end of the month, the number and types of food and income assistance programs used by low income families, and factors associated with the number of family food servings.

Methods

A random sample of 25 percent of family members from six food cooperatives for low income families was selected, with 109 of 114 responding. Fifty families from the Hillsborough County Florida Expanded Food and Nutrition Education Program (EFNEP) who were not participating in the food cooperative were randomly selected to participate in the study; 12 did not participate and 10 more were randomly selected as substitutes. One home interview was conducted for each family.

The focus of the study was the household. Demographic data were collected with information on participation in 23 food and income assistance programs. The number of family food servings during the past week from a list of 27 food groups was collected. A serving was defined as the preparation and offering of a food group to family members; second and third offerings of the food during the same meal were not counted. A normally distributed additive score for 20 food groups was calculated (mean ± 1 SD: 24.7 ± 5.0; Cronbach's alpha of 0.76.)[17] The excluded food groups were oils, salty snacks, candy, sweet baked goods, soda, soup, and coffee.

Frequency analysis using Chi-square and T-tests for means were used to determine the characteristics of the participants of the two programs. Multiple regression was used to determine factors related to the number of food servings. Potential independent variables for the final model were: participation in individual food and income assistance programs; the number of income or food assistance programs; the reference week of the month for the servings; the household size; sex of respondent; the age of the household respondent; participation in the food cooperatives or EFNEP; and an interaction term between program participation and reference week. However, when the final regression model was constructed several variables were not significant and dropped.

Results

The EFNEP households compared with the food cooperative families were younger: (31 vs 51 years); had more single parents (60 percent vs 40 percent); had more children less than 5 years of age (60 percent vs 44 percent); and had lived less time in their present location (42 vs 128 months).

The food and income sources used by these families are presented in Table 1. There was a wide variation in the combination of sources used among all families with no two families using the same combination; 39 percent had four or more sources and 13 percent had six or seven sources of income.

The last week of the month was associated with a decrease in the number of food servings per week (mean ± 1 SEM 22.9 ± 0.8) compared with the second (26.4 ± 1.0) and third (26.1 ± 0.8) week of the month (Figure 1). The variables in the best model (Table 2) to predict the number of food

SSI	32	10
Social Security	46	10
Wages	15	27

a) Programs that had less than 10% of participating families included soup kitchens, shelters, senior centers, meals on wheels, credit from stores, retirement funds, veterans, and loans.

TABLE 2—Regression Model to Predict Number of Meals Served in Household during Past Week

	Regression Coefficient	Standard Error
Intercept = 21.7		
WIC[a]	2.3	1.2
Household Size[b]	0.7	0.2
No. Income Sources[c]	1.2	0.4
Week of Month[d]	−0.7	0.4
Week Program[e] Interaction	−0.6	0.1

$F = 14.4$, $r^2 = 0.33$

a) A value of 1 was given to families who participated and a score of 0 for families who did not participate.

b) Household size was a continuous variable.

c) Number of income sources was a continuous variable.

d) Week of the month was a categorical variable that represented the reference week of the month (first to fourth) for the food servings.

e) The interaction term between families from two programs (food cooperative and EFNEP) and the reference week of the month for food servings.

servings per week were: participation in WIC, number of income assistance programs, number of people in the household, week of the month, and an interaction between the week of the month and participation in either the food cooperatives or EFNEP. This interaction represents a greater decrease in the number of food servings the last week of the month in the EFNEP families compared with the food cooperative families.

Discussion

The results from this study support previous reports that end of the month food shortages occur in low income families.[12,18-20] The significant interaction term for the number of food servings identified the EFNEP families who were younger, with children, and less established at their current location as one group at particular risk.

Our study also provides evidence that participation in a greater number of income assistance programs was associated with food servings. However, even after controlling for these factors there was a significant decrease in the number of food servings at the end of the month. This implies that current government support may not be sufficient to last an entire month, especially when the assistance is given one time at the beginning of each month. Several studies of food stamps recipients reported that families use their monthly allotment before the end of the month.* Even families who participate in five different programs have been reported not able to meet the thrifty food plan.[20] Nevertheless, even though there is no guarantee that the diets of families participating in federal programs are of high nutritional quality,[21] assistance programs have been shown to improve the diets of low income families and improve food security.[22]

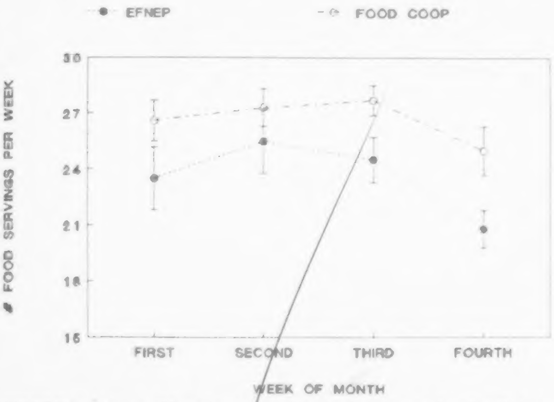

FIGURE 1—Number of Food Servings per Week in Low Income Families (Values represent the adjusted means for the number of servings per week; the vertical bars represent ± 1 standard error.)

In conclusion, weekly food servings decreased the last week of the month for these families and could be measured using a food frequency questionnaire. This pattern may be related to insufficient funds that occur the last week of the month when financial assistance from government sources are depleted.

ACKNOWLEDGMENTS

This study was supported by funds from the Tampa United Methodist Centers and the Hillsborough County Expanded Food and Nutrition Education Program (EFNEP). It was presented at the 1989 Annual Meeting of the American Public Health Association, Chicago, October 24, 1989.

The authors wish to thank the EFNEP workers and Food Cooperative workers who conducted the home interviews and the participants of these programs who cooperated with the study.

The Buddy Volunteer Commitment in AIDS Care

PRISCILLA VELENTGAS, CHRISTIAN BYNUM, AND SALLY ZIERLER, DRPH

Abstract: Buddy volunteers provide crucial assistance to people with HIV-related illnesses. Based on volunteers' self-administered questionnaires, our study describes the nature of buddy work. Volunteers indicated their satisfaction with both personal performance and buddy program administration. Several factors were associated with volunteer satisfaction. This report is a first attempt to describe this special relationship created in response to the human immunodeficiency virus (HIV) epidemic. (*Am J Public Health* 1990; 80:1378–1380.)

Introduction

Since the onset of the AIDS (acquired immunodeficiency syndrome) epidemic a decade ago, community-based support for people living with AIDS has increased. Formation of community-based organizations to help people with AIDS (PWAs) has taken place across the United States. Services provided range from food distribution to information hotlines to legal and political advocacy. The size of these organizations ranges from a few dozen active volunteers to several hundred.

This report focuses on programs that establish a special relationship between volunteer and client. "Buddy programs" pair a volunteer from the community with a PWA. The buddy volunteer gives his/her client companionship and basic assistance in living with AIDS, and performs tasks ranging from housekeeping to providing emotional support.[1,2] Thousands of volunteers across America have entered into this profound commitment which often lasts through the death of the person with AIDS.[3]

We attempted to investigate the work done by volunteers at one intermediate-sized AIDS project to determine the nature of the contact existing between the volunteers and the project and between the volunteers and their PWA clients.

Methods

Study Populations

To be eligible for this study, women and men must have completed a buddy training program offered by Rhode Island Project/AIDS prior to February 1989. This process included completion of an application and participation in a multiphase training program. One hundred forty-three past and present buddy volunteers were eligible for the study. To be in the study, active and former volunteers returned a self-administered questionnaire. This report is based on information from the 67 volunteers who completed the questionnaire.

Data Collection

An anonymous, self-administered questionnaire was distributed to all active and inactive buddy volunteers. Initially, questionnaires were coded to be matched with the volunteers' initial applications to the program so comparisons could be made between questionnaire and application data. Buddy support group leaders distributed the questionnaires. Inactive volunteers were mailed a questionnaire, along with a cover letter and a self-addressed stamped envelope, to their last known address.

To improve response, a second batch of questionnaires was distributed to group leaders with instructions to mail them back directly to the investigators. Inactive volunteers

This paper, submitted to the Journal September 15, 1989, was revised and accepted for publication March 7, 1990.

who had not previously returned a questionnaire were sent another one with a second cover letter.

Data Analysis

Active and inactive populations were examined together. Satisfaction with various aspects of program administration and with personal performance as a buddy volunteer was the conceptual outcome of interest. A satisfaction score was devised to classify respondents as satisfied, dissatisfied, or indeterminate. To quantify an individual's satisfaction, we created a five-point scale relating to a volunteer's levels of satisfaction with program administration and personal performance as a buddy; among these items were queries into the nature and perception of typical requests clients made to buddy volunteers, such as help with cleaning, transportation, or meal preparation. Other questionnaire items were examined in relation to this scaled outcome.

Most differences between the two groups were observed through the comparison of proportions. Satisfaction prevalence ratios were examined for certain determinants, namely lag time between becoming a buddy and being assigned a client, number of the client's total requests for specific buddy services per week, and volunteer's assessment of client's supportive relationships. Confidence intervals for these measures were calculated using Miettinen's test-based procedure.[4]

To evaluate whether the segment of the buddy volunteer population responding to the questionnaire was representative of the buddy volunteer population as a whole, data from the applications of buddies known to have responded to the questionnaire (in the first mailing) were compared to data collected from applications of the nonrespondents.

Results

Volunteer and Client Profiles

Fifty-three percent of buddies responding to the questionnaire were male, and most volunteers (73 percent) were 26 to 45 years old. Of 61 buddies identifying with a specified race category, only five (8 percent) reported themselves as other than White. When compared with AIDS cases in Rhode Island or with the client population, minorities were underrepresented among the volunteers. According to Rhode Island Project/AIDS, their buddy program serves 63 percent of the state's IV (intravenous)-drug-related AIDS cases.

The Buddy Experience

Tables 1 and 2 show distributions of experiences as buddy volunteers: Table 2 focuses on the weekly requests that are made to volunteers from their clients; Table 1 shows most buddies responding had been assigned at least one client; over 20 percent had been assigned two or more. Over one-third of buddies had experienced the death of a client. Few buddies had requested reassignment while their clients were alive. Over half of buddies reported that being a buddy had increased the stress in their lives.

The most significant problems faced in working with PWAs were the time commitment and emotional investment (Table 1). Dissatisfied buddies reported more requests for certain kinds of tasks than satisfied volunteers, such as cleaning and preparing meals (Table 2). Almost all the buddy volunteers visited their client at least once weekly. Over half provided transportation at least once per week. Shopping, cleaning, and preparing meals were done less often. Table 3 shows a distribution of the hours spent per week by buddy volunteers according to satisfaction status. Over 60 percent of volunteers spent six or more hours weekly providing buddy services.

*All percents are rounded to the nearest whole number; totals may not equal 100%.

**"Overall" includes all respondents to the question: "satisfied," "dissatisfied," and intermediate.

Buddy volunteers were twice as likely to report feeling satisfied if assigned to their first PWA one to five months after acceptance to the Buddy Program at Rhode Island Project/AIDS (prevalence ratio = 2.0; 95% confidence interval = 0.8,

TABLE 3—Distribution of Total Hours Devoted to Buddy Work by Satisfaction Status [number in category/number of respondents (percent)*]

# Hours per Week Devoted	Satisfied N (%)	Dissatisfied N (%)	Total N (%)
≤5 hours/week	7/19 (36)	12/31 (39)	19/50 (38)
6–10 hours/week	6/19 (32)	6/31 (19)	12/50 (24)
≥11 hours/week	6/19 (32)	13/31 (42)	19/50 (38)

*All percents are rounded to the nearest whole number; totals may not equal 100%.

5.1). Volunteers with 10 or less requests per week from their clients also reported greater satisfaction (prevalence ratio = 3.2; 95% ci = 1.5, 6.0). Buddies serving PWAs with more supportive relationships (other than buddy-client) in their lives were twice as likely to be satisfied in their work (prevalence ratio = 2.0; 95% ci = 0.8, 4.7).

Discussion

This study may be the first attempt to describe the work of AIDS volunteer programs such as the buddy program of Rhode Island Project/AIDS. Comparison of buddy/client and client/state AIDS case demographics suggest that minorities are underrepresented in these volunteer populations. While none of the volunteers responding to our questionnaire reported themselves as representing the Latino population, Rhode Island Project/AIDS' proportion of Black and Latino clients (25 percent)[5] is comparable with the state's proportion of Black and Latino cases (29 percent).[6]

This study describes the variety of services performed by buddy volunteers, and their interaction with the agency. Although there was considerable comparability between respondents and nonrespondents with respect to motivation for volunteering and providing support as buddies, we are cautious about generalizing the survey findings because the response rate was low.

The Buddy Program is a valuable, volunteer-based health care service that is critically needed by people with HIV (human immunodeficiency virus)-related illnesses. This description may stimulate increased appreciation of this service as well as promote an understanding of how to organize volunteers' efforts and support their needs.

Epidemiology of Reported Cases of AIDS in Lesbians, United States 1980–89

Susan Y. Chu, PhD, James W. Buehler, MD, Patricia L. Fleming, PhD, and Ruth L. Berkelman, MD

Abstract: National surveillance data for reported cases of acquired immunodeficiency syndrome (AIDS) were used to assess demographic characteristics and behavioral risk factors in lesbians. From June 1, 1980 through September 30, 1989, 79 women with AIDS reported sex relations only with a female partner; most of these women (95 percent) were intravenous drug users. Prevention of human immunodeficiency virus (HIV) infection in the lesbian community will require efforts to prevent and reduce intravenous drug use. (*Am J Public Health* 1990; 80:1380–1381.)

Introduction

Very little has been written on the epidemiology of acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection in the lesbian population. Two instances of female-to-female sexual transmission of HIV have been reported,[1,2] and there is some concern that the risk of infection in female homosexuals may be underestimated because of the lack of information about this population group.[3] This report describes various demographic characteristics and behavioral risk factors of lesbians with AIDS in the United States.

Methods

We used national surveillance data for 9,717 cases of AIDS in adult women reported to the Centers for Disease Control (CDC) between June 1, 1980 and September 30, 1989. Only those that met the CDC surveillance case definition for AIDS were included in our analysis.[4] AIDS patients were grouped according to their reported sexual behavior, using responses to the following two questions:

- "After 1977 and preceding the diagnosis of AIDS, did this patient have sexual relations with a male partner?"
- "After 1977 and preceding the diagnosis of AIDS, did this patient have sexual relations with a female partner?"

From the Division of HIV/AIDS, Center for Infectious Diseases, Centers for Disease Control, Atlanta. Address reprint requests to Susan Y. Chu, PhD, HIV/AIDS, Center for Infectious Diseases, GZ9, CDC, Atlanta, GA 30333. This paper, submitted to the Journal December 27, 1989, was revised and accepted for publication March 26, 1990.

Women who had sexual relations only with female partners were classified as lesbian, women who had both male and female sexual partners were classified as bisexual, and women who had only male sexual partners were classified as heterosexual. For women who were classified as lesbian, recorded data (e.g., sex, sex partners, mode of transmission) were confirmed directly with the reporting health departments to minimize misclassification and data entry errors. We excluded 1,242 women who could not be classified as lesbian, bisexual, or heterosexual because of incomplete responses to the above two questions. However, 90 percent of these women had a known risk for HIV exposure (intravenous drug use, heterosexual contact with a person at increased risk for, or known to be, infected with HIV, or blood transfusion).

Persons with AIDS were classified in a hierarchy of exposure categories according to their presumed means of acquiring HIV infection. Those with more than one possible means of acquisition were classified only in the exposure listed first in the hierarchy, by using the following sequence: 1) intravenous drug use, 2) receipt of blood products, 3) heterosexual contact with an HIV-infected partner (or having a specified risk for HIV), and 4) "no identified risk." The last category represents persons who had none of the other risk exposures above, and therefore could include women who acquired HIV infection through female-to-female sexual contact.

Results

As of September 30, 1989, there were 79 reported cases of AIDS in lesbians, representing 0.8 percent of all reported adult women with AIDS in the United States.

As shown in Table 1, most of the lesbians with AIDS (95 percent) were intravenous drug users (IVDUs). The remaining 5 percent acquired HIV infection through the receipt of blood or blood products. As with IVDU-associated AIDS in all women, most lesbian women with AIDS were younger (85 percent were less than 40 years old), Black or Hispanic (80 percent), and resided in the northeast (77 percent). There were 103 reported cases of AIDS in bisexual women. Most bisexual women with AIDS also were IVDUs (79 percent), 16 percent had sex partners at increased risk or known to be infected with HIV, and 4 percent had histories of blood transfusion.

We also compared the occurrence of reported opportunistic diseases among homosexual, bisexual, and heterosexual women with AIDS. The only notable difference was in the occurrence of Kaposi's sarcoma (KS). KS (including presumptive and confirmed diagnoses) was not reported in any of the homosexual females with AIDS but was reported in 9 percent (9/103) of bisexual females and 2 percent (167/8,293) of heterosexual females with AIDS.

Discussion

Lesbians represent a very small proportion of women with AIDS in the United States, and most cases are related to intravenous drug use. Prevention of HIV infection in the lesbian community will require efforts to prevent and reduce IV-drug use—the major and most direct means of transmission in this population.

Although there is no specific exposure category for female-to-female transmission, lesbians who acquired HIV infection from female-to-female contact would have been classified in the "no identified risk" (NIR) exposure category, of which there were none. Female-to-female transmission of HIV also could occur among bisexual females; however, only one bisexual female had no identifiable risk and was classified in the NIR category.

Although it is not possible to determine whether differences in the occurrence of Kaposi's sarcoma (KS) reflect differences in exposures, we also observed that among women with AIDS who reported sex with a *bisexual* man, 4.1 percent (20/493) had KS reported, whereas among women who did not report sex with a *bisexual* man, 1.6 percent (52/3162) reported KS. Moreover, the frequencies of reported KS were higher among homosexual (22 percent) or bisexual men (14 percent) than among heterosexual men (3 percent) (whose predominant means of HIV exposure was intravenous drug use). These patterns are compatible with the hypothesis that KS is a sexually transmitted infection that occurs in association with HIV infection and disproportionately affects homosexual and bisexual men.[5]

It is important to note that we used categories based on reported sexual behaviors, not on self-labeled sexual orientation. The labels "heterosexual" and "homosexual" do not always predict sexual behavior.[6] Our "lesbian" category does not necessarily represent women who identify themselves as lesbians, but more accurately represents women with AIDS who reported having sexual relations only with a female partner since 1977.

Although female-to-female transmission of HIV appears to be an extremely rare event, the occurrence of AIDS among lesbian and bisexual women indicates that women who engage in sex with other women can be exposed to HIV. Case reports of female-to-female sexual transmission of HIV[1,2] and the well-documented risk of female-to-male HIV transmission indicate that vaginal secretions and menstrual blood are potentially infectious and that mucus membrane (e.g., oral, vaginal) exposure to these secretions can potentially lead to HIV transmission.

Prior Cesarean Delivery in Women with Secondary Tubal Infertility

Marsha E. Wolf, PhD, Janet R. Daling, PhD, and Lynda F. Voigt, PhD

Abstract: The history of cesarean delivery was evaluated in a population-based case-control study of secondary infertility in King County, Washington. Sixty-one married women diagnosed with secondary infertility due to tubal problems who had a previous viable pregnancy were compared to 343 married women who had a previous viable pregnancy and then had a live birth that was conceived at the same time the infertile women began trying to conceive. The risk of tubal infertility was not substantially elevated in women who had a previous cesarean delivery in the most recent viable pregnancy compared to women with vaginal delivery (odds ratio = 1.2; 95% confidence interval = 0.4, 3.7). (*Am J Public Health* 1990; 80:1382–1383.)

Introduction

Cesarean section deliveries in the United States have increased from 5.5 per 100 deliveries in 1970 to 20.3 in 1983.[1,2] Women who have cesarean deliveries are at greater risk for postpartum complications of pelvic infections than women who deliver vaginally,[3] but the effect of cesarean delivery and related postpartum infection on subsequent fertility is not well understood.[4–10]

Methods

A case-control study design was used, in which the cases were 61 20–39 year old married women residents of King County, Washington who had secondary infertility (women who had previously conceived, but who were not able to conceive after trying for at least one year) and who have previously delivered a live birth or still birth. These women had their first medical evaluation for infertility during 1979 to 1981. (The study subjects were part of a larger study on infertility and contraception in which 89.5 percent of all physicians in King County who perform infertility evaluations agreed to participate.)[11] If cesarean section via a possible infection did lead to infertility in some women, it would more likely be women whose infertility was related to a tubal condition.[12,13] For this reason only women with blocked tubes, diagnosed by hysterosalpingogram or surgery, were included as cases. Women with an abnormal hysterosalpingogram who were later found by surgery to have an intrauterine abnormality, rather than a tubal condition, were excluded.

The control group (n = 343), identified from state vital records, was composed of 20–39 year old married women residents of King County who had a previous birth and then subsequently delivered a newborn who was conceived during the same years in which the infertile cases started trying to become pregnant.

By structured interview, data for each study subject were collected on demographic characteristics, use of "social" drugs, tobacco, alcohol, personal hygiene, and medical, reproductive, contraceptive, and sexual histories.

Results

Although cases and controls were somewhat similar with regard to education, income, and age at reference date (the time at which both the infertile case and the control began to attempt to conceive), the cases had a larger percentage of racial minorities and were more likely to have been employed, to be a smoker, and to have had more sexual partners, a history of Dalkon Shield use, and their last viable pregnancy before 1975 than did the controls (Table 1).

A cesarean section delivery of the most recent birth was found in four cases (6.6 percent) and in 29 controls (8.3 percent). Using unconditional logistic regression to obtain maximum likelihood estimates of relative risk, we adjusted for the effects of age (less than 30, 30 or older) and year of last viable pregnancy (before 1975, 1975 or after). The adjusted odds ratio, an estimate of the relative risk, was 1.2 (95 percent confidence interval = 0.4, 3.7). Since the number of exposed cases was small, we also performed exact stratified analysis with EGRET statistical software which utilizes the method described by Mehta, Patel and Gray.[14] The exact odds ratio, adjusted for the same variables as above had slightly wider confidence intervals (OR = 1.2; 95% CI = 0.3, 3.8). Variables that were assessed but did not appreciably change the cesarean delivery risk estimates included race, employment type, smoking status, parity, education, income, age at first coitus, number of lifetime sexual partners, history of Dalkon Shield and other intrauterine device use, history of gonorrhea, pelvic inflammatory disease, douching, marijuana use, and census tract of residence.

In our study, no case or control with a cesarean delivery reported postpartum pelvic infection.

Discussion

Although this study revealed no association between cesarean delivery and subsequent secondary tubal infertility, the small sample size limited the study's ability to detect a possible modest increase in risk associated with cesarean delivery. The 95% CI suggests a relative risk of 3.7 or more is highly unlikely.

Another limitation of the data is that women with a prior successful pregnancy who had a cesarean delivery may be less motivated to seek help or to undergo the expense or discomfort of invasive techniques, i.e. hysterosalpingogram or laparoscopic surgery necessary to diagnose tubal infertility. To the extent this is so, ascertainment of cases of women with secondary tubal infertility among women with cesarean section will be incomplete, and the observed risk will underestimate the true risk.

Finally, we were unable to assess the more direct measure of post-cesarean pelvic infection itself, except by self-report. Medical charts were not reviewed.

[a] Two cases and two controls did not answer this question.
[b] One control refused to answer.

Despite these limitations, this study adds to our knowledge; it is the first reported population-based case-control study which assesses the relative risk of secondary infertility following cesarean section. Our findings corroborate those of Hemminki, *et al*,[4] and Zdeb, *et al*,[6] who found essentially no difference in the proportion of women who had at least one subsequent child after the first pregnancy when comparing women with previous cesarean and vaginal deliveries.

The findings are in contrast to those found by La Sala[7] and Hemminki.[5] Of all the reported studies, only La Sala adequately excluded women who had been sterilized, were using contraceptives, or were not attempting a pregnancy. However, La Sala defined secondary infertility as two years of infertility, a definition not widely used in the United States.

Three other studies that addressed this topic found similar rates of subsequent pregnancies in women with emergency cesareans[9] or cesareans with subsequent infection[8,10] compared to other women with elective cesarean or cesarean without infection respectively.

One explanation for why a large increase in risk of infertility was not found in our study may be prophylaxis or early diagnosis and treatment of postpartum infections in women with cesarean deliveries which could prevent the severity and course of infection and thus decrease the occurrence of tubal damage.

It will take larger studies or several studies to be confident in these results. It is nonetheless reassuring that in a metropolitan area of nearly 1.3 million people in which most of the incident cases of infertility who sought help were identified, only four of the 61 cases of secondary tubal infertility with a prior live birth had a cesarean section in the last delivery, a rate similar to the comparison group and to obstetric patients seen during the same time period.

A Comparison of Homeless, Community-wide, and Selected Distressed Samples on the CES-Depression Scale

Ferris J. Ritchey, PhD, Mark La Gory, PhD, Kevin M. Fitzpatrick, PhD, and Jeffrey Mullis, MA

Abstract: Center for Epidemiological Studies (CES) Depression Scale results for surveys of homeless, community-wide and selected distressed samples are compared. Nearly four times the percentage of homeless fit the criterion for clinical caseness (a score of 16+) compared to the general population (74 to 19 percent). None of the distressed samples exhibited a higher rate except psychiatric patients diagnosed as acutely depressive. High rates of depression have implications for social policies directed toward homelessness. (*Am J Public Health* 1990;80:1384–1386.)

Introduction

Psychological depression is characterized by depressed mood, negative self-concept, disturbed vegetative functioning, agitation, slower activity levels, distractibility, and indecisiveness.[1] These symptoms of extreme distress are especially detrimental for problem solving and coping among homeless persons with few financial and social resources, and limited control over their environments.

The Center for Epidemiological Studies Depression Scale (CES-D)[1-3] is a survey instrument scored from 0 to 60 (20 symptoms coded 0 to 3 depending on their frequency during the week prior to interview). It has high internal consistency,[1] strong test-retest reliability[4] and, although designed to measure depressive symptomatology in community populations, it is a sensitive predictor of diagnosed depression.[4-7] For example, Boyd, *et al*, found 80 percent correspondence between diagnosed depression and "possible clinical caseness" (a CES-D score of 16+).[8] The scale's specificity is strong; over 91 percent were correctly predicted to have nondepressive diagnosis (using the Diagnostic Interview Schedule) when the 21+ cutoff was used for the CES-D.[4] For our homeless sample, the Cronbach's alpha reliability coefficient for the CES-D was .89; item-to-total correlations ranged from .24 to .74.

Using the CES-D Scale,[1-3] we compared rates of depressive symptoms for a sample of homeless persons to existing data on community-wide and selected distressed samples.

Methods

Data on the homeless were from the Birmingham (Alabama) Homeless Enumeration and Survey Project conducted in early 1987.[9] The Metropolitan Statistical Area (MSA) population was approximately 900,000. The enumeration phase was a single-night census of homeless persons finding 498 in MSA shelters, and 103 on the streets downtown where the homeless were known to be concentrated. An interview survey of 150 adults followed in the three months after the enumeration. A random probability sampling design was used with quotas for the variables sex, race, and geographic site (i.e., shelter versus street) based on enumeration data. Whites were slightly overrepresented in the street sample. Interviews averaged 62 minutes. Of 155 people asked for interviews, only one refused. Four interviews were unusable.

Results

Table 1 presents percentages of possible clinical caseness (CES-D of 16+) for community-wide, selected distressed, and homeless samples.* Across five general population studies in various communities between 1971 and 1985, the results fell consistently below 20 percent. In the distressed samples (discounting acute depressives), percentages ranged from 23.0 (physically or psychologically impaired persons over 55) to 79.0 (rural mental health clinic patients). Generally, the distressed samples comprised of psychiatric patients had higher rates than samples characterized by stressful life circumstances.

Comparing community-wide and distressed samples to our sample revealed a considerable amount of distress among the homeless. Only one respondent of our sample was asymptomatic. Nearly three of four (73.3 percent) scored 16 or above. This percentage was similar to Koegel and Burnam's[14] finding of 71 percent clinical caseness among homeless males of inner-city Los Angeles. In addition, we found 37 percent to score 30 or above, a result similar to Susser's 33 percent for a sample of male first-time shelter users primarily under 40 years of age.[19] Except for Weissman's study of clinic patients diagnosed with acute depression,[6] even groups as distressed as psychiatric inpatients, alcoholics under treatment, and rural mental health clinic patients did not have significantly higher rates.

Comparisons to domiciled samples with stressful life circumstances were informative. For example, low income mothers of young children had significantly lower rates than the Birmingham homeless, as did the unemployed, suggesting that environmental and situational stressors of homelessness exact a greater toll on mental well-being than those faced by the housed poor. Finally, for persons recently widowed or separated—two highly stressful life events—the rates of clinical caseness were lower than that of the homeless sample. An analysis elsewhere of variation in depressive symptomatology within our homeless sample revealed that homelessness does not impact its victims differentially.[20] No matter how the sample was broken down, the mean CES-D score for any subsample was more than twice the mean score of any of the community-wide samples.**

Discussion

The homeless suffer from high rates of depressive symptomatology indicative of extreme distress. Only acute depressives, mental health clinic patients, psychiatric inpatients, and alcoholics have rates of clinical caseness on the CES-D comparable to the homeless. Some caveats are in order. First, given the extreme environmental conditions of homelessness (e.g., poor nutrition, climatic exposure), the CES-D may be tapping physiological as well as psychological dimensions.[6] Second, the CES-D may be, for some respondents, gauging reactions to acute situational factors rather than gauging depressive illness or chronic demoralization.[13,21-24] Third, homelessness is usually accompanied by other stressful life events and circumstances; thus, depression may precede homelessness in some cases.[24] Notwithstanding these considerations, depressive symptoms have implications for an individual's ability to resolve the situation, even if external conditions (e.g., available jobs and housing) are favorable. These results suggest that current shelter, rehousing, and treatment programs should institute intervention strategies to avert the potentially cyclical nature of homelessness and depression.

How Valid Are Mammography Self-Reports?

EUNICE S. KING, RN, PHD, BARBARA K. RIMER, MPH, DRPH, BRUCE TROCK, PHD,
ANDREW BALSHEM, BA, AND PAUL ENGSTROM, MD

Abstract: We compared mammography reports in medical records to self-reports obtained during a 1989 telephone interview survey for a sample of 100 women members of a health maintenance organization (HMO) who indicated they had mammograms within the past year and 100 who said they had not had mammograms within the past year. Of the women reporting they had not had mammograms within the past year, none had mammogram reports in the HMO data center. Of the 100 women reporting they had mammograms within the past year, 94 had confirmatory radiology records. (*Am J Public Health* 1990; 80:1386–1388.)

Introduction

Programs of regular mammography screening can produce downward shifts in the stage of breast cancer and reduce mortality by as much as 35 percent.[1–4] The National Cancer Institute (NCI), the American Cancer Society, and other major medical organizations recommend annual screening mammograms for all women ages 50 and older and screening every one to two years for women ages 40–49 years.[5] A potential problem in evaluating the effectiveness of programs aimed at increasing mammography utilization is that most surveys and program evaluations have relied exclusively upon women's self-reports of mammograms. The draft of the US Department of Health and Human Services' Year 2000 Objectives for the Nation stipulates that one of the key assumptions underlying the tracking of changes in mammography utilization is that self-report data provide a valid measure of screening utilization.[6]

If mammography self-reports are not accurate, survey data may overestimate or underestimate actual mammography utilization. Although the accuracy of self-report data in such diverse areas as cervical cancer screening and smoking cessation has been studied,[7–11] the findings cannot be generalized from one content area to another.[7] Based on a MEDLINE search, we found no published studies in which mammography self-reports were validated. Therefore, we undertook the present study.

Methods

This validation study was part of the Avoidable Mortality Study,[4] conducted in conjunction with US Healthcare Check, a free breast screening program offered to all women members of an IPA-model (independent practice association) HMO (health maintenance organization) ages 40 years and over. National guidelines are followed: mammograms are recommended every one to two years for women ages 40 to 49 years and annually for women age 50 and older.[5]

Four telephone survey waves are conducted as part of the Avoidable Mortality Study to evaluate the effectiveness of the program in increasing mammography utilization among women in the HMO compared to geographic controls. US Healthcare Check maintains a centralized mammogram report database. Radiology reports of HMO members are sent to the US Healthcare Check office and to the women's physicians.

In January 1989, a telephone survey was conducted as part of the Avoidable Mortality Study. A sample of 450 HMO women between the ages of 50 and 74 was selected randomly from approximately 45,000 eligible women to whom the US Healthcare Check program is targeted. Interviews were completed with 84 percent; fewer than 10 percent of the women refused to be interviewed.

During the 15-minute structured telephone interview conducted by professional interviewers, women who said they had mammograms were asked when the procedure was most recently done. Mammography utilization questions were those used in the National Health Interview Survey (NHIS) 1987 Cancer Control Supplement and by members of the NCI's Breast Screening Consortium.[4] Overall, 63 percent of the HMO respondents said they had a mammogram in the past year. Mammography rates similar to those in our study and higher than the NHIS[12] also were found in surveys

conducted by five other NCI Mammography Consortium sites.[13] We questioned whether overreporting could account for some of these differences.

In August 1989, we randomly selected 100 women from the 278 HMO women whose responses indicated they *had* a mammogram within the past year and 100 HMO women from the 171 who indicated they *had not had* a mammogram within the past year. These women comprised the validation study sample.

For women reporting having had mammograms within the past year, project staff contacted the HMO assigned radiology center if the database contained no confirmatory record. If the center was unable to verify the woman's mammogram through radiology reports, the primary physician was identified through the database and contacted. If the physician had no record of the mammogram, the woman herself was contacted to provide additional information about where and when she had the mammogram. Subsequently, with the woman's consent, study staff contacted the radiology center indicated for confirmation of the mammogram. In all instances, women's self-reports were considered valid only if they reported having had a mammogram, and this report was validated by database information or confirmed by radiology or physician's office records.

Results

Of the 200 women originally selected for the validation study, one had to be eliminated due to a data entry error. In general, women reporting having had a mammogram within the past 12 months did not differ from those reporting not having had a mammogram within the past 12 months. However, working women were significantly less likely to have obtained mammograms, and there were more employed women in the group who had not had mammograms (Table 1).

Women's self-reports of having obtained mammograms within the past year correlated highly with the presence of actual mammogram reports (Table 2). Of the 99 women reporting they had *not* had mammograms within the past year, none had a mammogram report in the database. Of the 100 women reporting they "had a mammogram" within the past year, we were able to validate self-reports on 94 women. Mammogram reports on 50 of these women were obtained through the database; the remaining 44 were validated through phone calls to radiology centers or to the women's physicians. Although *all* of the remaining six women had obtained mammograms, they were not done within the past year. Five of the women had mammograms between 13 and 18 months prior to the survey interview; the other woman had a mammogram two years prior to the survey. These six women did not share any particular sociodemographic characteristics when examined by age, employment, race, education, and marital status. Thus, ultimately, we were able to account for *every* one of the women who reported that they had mammograms.

Discussion

These data indicate agreement between women's self-reports of mammography and providers' records. But, for the 99 women reporting they had *not* had mammograms within the past year, we did not attempt further verification beyond the data in the US Healthcare Check database, as we did for the women reporting they had obtained mammograms within the past year.

*Numbers do not equal total n due to refusals or missing data.

It is not feasible to verify such negative reports beyond the HMO database, since it would require contacting every physician who could have ordered a mammogram for each woman. At first, only 50 percent of women who reported having a mammogram had verification in the HMO database. These omissions were due to the radiologist failing to report the procedure in a timely fashion; the women had responded correctly. For a similar rate of omission to exist among the women reporting *not* having mammograms would also require an error in self-report on the part of the majority of women. Given the high rate of accuracy among women reporting mammograms, a high rate of inaccurate response among women reporting no mammogram seems highly unlikely.

In a study by Sawyer, *et al*,[11] of the accuracy of women's self-reports of Pap tests, the underreporting errors—although less than the overreporting errors of 21 percent—were 17

TABLE 2—Comparison of Women's Self-reports with Actual Mammogram Reports

percent. Unlike having a Pap test, which is usually taken only during a pelvic examination, and sometimes without the woman's knowledge, having a mammogram is a discrete event which occurs at a time or a place other than the medical examination and thus is less likely to be confused or forgotten.

Although further studies in other populations should be done to confirm the results found here, these data provide a basis for optimism. If the findings are replicated, it appears that women's self-reports can be used accurately to monitor national changes in mammography utilization.

Incidence of Bicycle-Related Injuries in a Defined Population

DIANE C. THOMPSON, MS, ROBERT S. THOMPSON, MD, AND FREDERICK P. RIVARA, MD, MPH

Abstract: Population-based incidence rates for head injuries and total injuries resulting from bicycle crashes were calculated in a Seattle, Washington health maintenance organization population. Overall rates were 163 per 100,00 for all injuries and 42/100,000 for head injuries. Individuals between 5 and 14 years of age are at highest risk for bicycle-related injuries. The data are presented for their potential utility in program planning. (*Am J Public Health* 1990; 80:1388–1389.)

Introduction

Bicycling is an increasingly popular sport in the United States. Injuries due to bicycling accounted for approximately 574,000 emergency room visits and 1,300 deaths in 1985, with head injuries accounting for the major morbidity and mortality.[1,2] Helmets have been shown to be an effective means of preventing these injuries.[3] Programs to promote helmet use have been successful.[4] The present study was undertaken to provide information on the incidence of these injuries for use in community bicycle helmet campaigns and safety programs.

Methods

Injured cyclists were identified during a one year surveillance of hospital emergency rooms in Seattle, Washington (December 1, 1986 to November 30, 1987). The methods are detailed elsewhere.[3] Cyclists for this study are limited to those treated at the facilities serving Group Health Cooperative of Puget Sound (GHC), a large staff-model health maintenance organization, thus allowing the calculation of population-based rates. GHC membership is demographically similar to the surrounding population in the Seattle metropolitan area, but differs from the US population by its greater educational level and underrepresentation of Blacks. Group Health Cooperative members are highly educated; 67 percent have more than a high school education. The ethnic composition of GHC membership is 91 percent Caucasian, 3 percent Black, 4 percent Asian/Pacific Islander, and 2 percent other, compared to 83.4 percent, 11.7 percent, 1.7 percent, and 3.2 percent, respectively in the US population.

GHC Central and East regions include 223,298 members who receive nearly all their outpatient, emergency, and hospital care at GHC facilities. There were two severely injured cyclists treated at the regional trauma center; these were included in the study. Review of the medical examiners' records for the study period indicated no deaths at the

Thompson is Senior Director of Preventive Care Research, Department of Preventive Care, Group Health Cooperative of Puget Sound; Dr. Rivara is Director of Harborview Injury Prevention and Research Center, as well as Professor of Pediatrics and Adjunct Professor of Epidemiology, University of Washington School of Medicine. This paper, submitted to the Journal December 11, 1989, was revised and accepted for publication April 9, 1990.

accident scene. Bicyclists injured outside the Seattle metropolitan area or treated at other area medical facilities were not included.

Exposure to cycling was measured by asking the frequency of riding and the number of miles and hours cycled per week. Self-reported mileage figures were used to calculate the mean number of miles cycled per week, and to estimate injuries per 100 miles ridden.

Incidence rates of emergency room treated injuries resulting from bicycle crashes were calculated using the mid-year 1986 population of the GHC East and Central regions.

Results

There were 364 Group Health members treated in the emergency room for bicycle-related injuries. One hundred-one (28 percent) were head injured. Thirty (29.7 percent) of the head injured experienced brain injuries; 4 percent were hospitalized. The 364 cyclists constituted 54.5 percent of all cyclists seen in the five area hospitals.

Table 1 displays age- and sex-specific injury rates. Head injury rates were highest in the 5–9 year age group while rates for all bicycle injuries were highest in the 10–14 year age group. Males had higher injury rates than females. When the incidence of bicycle-related injuries was age-adjusted to the US population, the rate was 51 per 100,000 for head injuries and 187 per 100,000 for all bicycle injuries.

Fifty-six of the 364 injured cyclists (15.4 percent) were wearing helmets at the time of the crash; only seven of the 56 head-injured were helmeted. Helmet use was very low among riders under 15 years of age (4.3 percent), but increased to 23 percent among 15–24 year olds and to 44 percent for those 25 years of age and older. There were no significant differences in rates of helmet use by sex.

Exposure to cycling is summarized in Tables 2 and 3. The injury rate per 100 miles ridden per year is highest for 5–14 year olds. Seventy-seven percent of the ER visits were between April and September.

Discussion

Although helmet use has a direct effect on head injuries,[3] it does not explain why the peak ages of head injuries and overall injuries are different or why the ratio of head to all injuries is higher for young children. Our cycling exposure data, which are similar to those of other studies[1,5–7], do not explain the differences. Possible explanations are differential ascertainment of injury types and increased injury severity in older children.[8]

We assume most cycling mileage was estimated based on distance between destinations rather than actual measurement. The number of bicycle odometers used is unknown. Mileage data indicate children 5–9 years old are at highest injury risk.

Friede and co-workers (SCIPP) reported 87.8 bicycle injuries per 10,000 person years (0–19), with the injury rate highest in 6–12 year old males.[5] Our overall injury rate for this age group was 45 per 10,000. Reasons for the discrepancy are not clear. Lack of case ascertainment in the present work does not appear to be the explanation because it was a closed system of care. Other potential explanations for the differences include SCIPP'S use of all pedal cycle accidents (bicycles, tricycles, other pedal powered vehicles), sampling methods (SCIPP used a 25 percent sample of accidents over a two-year period),[5] and the proportion of all types of GHC injuries treated in the ER (40 percent) versus primary care (60 percent).[8] This latter study indicated that GHC overall rates (clinic and ER combined) appear closer to ER rates obtained by SCIPP[9] and NEOTS.[10] Two other studies[11,12] reported incidence rates of medically treated injuries similar to rates at GHC.[8] Waller (1971) reported higher bicycle injury rates. His denominator, all bicycle owners, yields higher rates than using the general population.[7]

Brain injury rates are comparable to other studies. Kraus, *et al*, reported population-based rates of brain injuries from bicycle crashes requiring hospitalization of 13.5 per 100,000 with the highest injury rates in children under age 15.[13] The rate for all brain injuries from the present work was 12.5 per 100,000.

The rates of injuries reported here are conservative since they represent only ER treated injuries. Many injured cyclists, possibly the majority, were treated at home or in outpatient clinics. Bicycling injuries contribute substantially to health care utilization and are a chief cause of recreational injury.[1,6,14–20] Children age 5–14 are at greatest risk of injury, and are an appropriate target for the application of available and effective prevention programs.[2,3,5,21]

The data presented are offered for their potential utility to the communities planning bicycle safety helmet campaigns.

Hypertension Prevalence and the Status of Awareness, Treatment, and Control in the Hispanic Health and Nutrition Examination Survey (HHANES), 1982–84

Gregory Pappas, MD, PhD, Peter J. Gergen, MD, MPH, and Margaret Carroll, MSPH

Abstract: The prevalence rates of hypertension among adult (ages 18–74) Mexican Americans, Cuban Americans, and Puerto Ricans were estimated using data from the 1982–84 Hispanic Health and Nutrition Examination Survey (HHANES). Hypertension is defined as diastolic greater than or equal to 90 mm Hg, or systolic greater than or equal to 140 mm Hg, or currently taking antihypertensive medication. Among Mexican Americans in the Southwestern United States, 16.8 percent of the males and 14.1 percent of the females were found to be hypertensive. Among Cuban Americans in Dade County, Florida 22.8 percent of the males and 15.5 percent of the females were hypertensive. Among Puerto Ricans in the New York City area 15.6 percent of the males and 11.5 percent of the females were hypertensive. The age-adjusted rates are significantly lower than comparable rates for Whites and Blacks as measured in the second National Health and Nutrition Examination Survey (NHANES II), 1976–80. Control of hypertension in the HHANES populations fall short of the 1990 Objectives for the Nation established by the US Public Health Service 60 percent (34 percent controlled Mexican American hypertensives, 27.8 percent controlled Cuban American hypertensives, and 29 percent controlled Puerto Rican hypertensives). (*Am J Public Health* 1990; 80:1431–1436.)

Introduction

Hypertension continues to be a leading contributor to morbidity and mortality in the United States.[1] While the number of studies on the extent and nature of hypertension in the US population has increased, our knowledge of how this condition affects Hispanics has lagged behind.[2] Hispanics are the second largest minority in the United States and constitute a rapidly growing population.[3] An assessment of risk factors for hypertension has suggested that Hispanics may have high rates of the condition.[2] Surveys which have estimated the prevalence of hypertension among Hispanics have given inconclusive results.[4–8]

The drive toward better blood pressure control has been heightened by the success measured in a decline in stroke and coronary artery disease mortality.[1] The US Public Health Service has set "1990 Objectives for the Nation" including nine dealing with hypertension control. The 1990 Objectives directed towards improving health status of hypertensives state that ". . . at least sixty percent of the estimated population having definite high blood pressure (160/95) or higher should have attained successful long-term blood pressure control, i.e. a blood pressure at or below 140/90 for two or more years."[9] The extent to which Hispanics have met these goals is unknown.

This paper provides estimates of the prevalence of hypertension among three Hispanics subgroups based on the Hispanic Health and Nutrition Examination Survey (HHANES) conducted by the National Center for Health Statistics between 1982 and 1984. These estimates are compared to the published results for Whites and Blacks in the general population using the second National Health and Nutrition Examination Survey (NHANES II), 1976–80.[10] The status of awareness, treatment, and control of hypertension among Hispanics has also been estimated using HHANES data.

Methods

Survey Design

The HHANES was conducted among three Hispanic subgroups in the United States from July 1982 through December 1984. The three target populations consisted of the civilian, noninstitutionalized population of Mexican origin or ancestry in selected parts of five southwestern states (California, Arizona, New Mexico, Colorado, Texas); of Cuban origin or ancestry in Dade County (Miami), Florida; and of Puerto Rican origin or ancestry in selected counties in New York, New Jersey, and Connecticut.

The survey design of HHANES was a stratified, multistage, probability sample of persons ages six months through 74 years. Selected households within the survey were visited by a bilingual interviewer who identified eligible Hispanic families. A pre-determined sampling pattern was followed to choose specified family members to participate in the survey. A family was considered eligible if the national origin or ancestry of at least one family member met the criteria (Mexican American in the southwest, Cuban American in

NHANES II:	Second National Health and Nutrition Examination Survey

Dade County, and Puerto Rican in the New York City area); however, the selected sample persons themselves were not necessarily of the same origin. Analyses in this paper are based on data only for those sample persons of Mexican origin or ancestry in the southwest, of Cuban origin or ancestry in Miami, Florida, and of Puerto Rican origin or ancestry in the New York City area.

Details of the HHANES sample design, selection process, operational plan, quality control procedures, and questionnaires have been previously documented.[11]

Data Collection

The HHANES included both a household interview and a physical examination conducted in a specially designed mobile examination center. As part of the household interview, sample persons were asked if they had ever been told by a physician or other health professional that they had hypertension and if they were currently using medication for treating hypertension. Upon completion of the household interview, participants were scheduled for a physical examination that included blood pressure measurement, conducted in the mobile examination center.

Systolic (first phase) and diastolic (fifth phase) blood pressure were measured to the nearest even digit using a standard mercury sphygmomanometer. Two blood pressure measurements were taken on one occasion in the mobile examination center as part of a physician's examination. Both measurements were taken with the patient seated, five minutes into the examination and five minutes apart. The average of the two readings was used for the estimates presented here.

Definitions

For the purpose of the prevalence estimates presented in this paper, persons are considered hypertensive if they meet one of the following conditions set by the 1988 Report of the Joint National Commission on Detection, Evaluation, and Treatment of High Blood Pressure (JNC 1988): 1) a diastolic blood pressure of greater than or equal to 90 mm Hg; 2) a systolic blood pressure greater than or equal to 140 mm Hg; 3) reporting currently using anti-hypertensive medication (regardless of blood pressure measurements).[1] The 1990 Objectives use a second definition for hypertension setting the thresholds at diastolic greater than or equal to 95 mm Hg and systolic greater than or equal to 160 mm Hg. This second definition for hypertension (160/95) is used to assess the levels of awareness, treatment, and control of hypertension.

Prevalence estimates for the specific categories of adult blood pressure levels follow the JNC 1988 guidelines. These categories are listed and defined in the Appendix. Blood pressure levels are reported as a percent of the HHANES target population and as a percent of the hypertensives in those populations.

Hypertension prevalence estimates are available for Whites and Blacks in the general population based on the NHANES II (1976–80). These estimates have been previously published in a report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure, 1984 (JNC 1984).[10] The JNC 1984 estimates for hypertension were based on the average of three pressures (taken with the examinee sitting, lying, and again sitting). A caveat for the comparisons is that the JNC 1984 estimates included a small number of Hispanics. However, the removal of Hispanics from the sample does not produce estimates that show statistically significant differences from the estimates published in JNC 1984 report.

The percent of hypertensives under control on medication is defined as: the number of hypertensives who report taking medication and whose blood pressure is less than the threshold of 140/90 mm Hg (numerator) divided by the total of the hypertensives (denominator). Control is reported as a proportion of both definitions of hypertension, using the 140/90 and 160/95 thresholds.

The higher threshold for hypertension determines the denominator for the status variables (awareness, treatment, control). A person is considered aware of their hypertension if they report having ever been told by a physician or other health professional that they have high blood pressure or hypertension. Those who report they are currently taking antihypertensive medication are considered treated.

Response Rates

Among those selected for HHANES and eligible (of Hispanic origin), ages 18 to 74 years, there were 5,130 Mexican Americans, 1,560 Cuban Americans, and 1,942 Puerto Ricans. Of the selected persons, the proportion of persons interviewed was 77.4 percent, 72.6 percent, and 77.9 percent for Mexican Americans, Cuban Americans, and Puerto Ricans, respectively. Two blood pressure measurements were obtained on 82.3 percent, 75 percent, and 77.7 percent of the interviewed persons in the Mexican American, Cuban American, and Puerto Rican samples, respectively. No significant differences were noted with regard to age, sex, and antihypertensive medication status between persons interviewed and persons with two blood pressure measurements in any of these subgroups.

Systematic Bias in BP Measurements

The tendency toward blood pressure readings ending in zero was identified as a problem in HHANES (diastolic 23.8 percent, systolic 27.6 percent). Further analysis of this systematic bias was made around the critical values used to define hypertension: 90 mm Hg diastolic and 140 mm Hg systolic. Diastolic 86 mm Hg and 88 mm Hg were read more often than either 90 mm Hg or 92 mm Hg. Systolic 140 was read more often than 138. Thus it appears that the examiners tended to read below the level defining hypertension on the diastolic reading and above the level defining systolic hypertension. Therefore, the previously noted systematic bias may be thought to have an equivocal effect on the point estimates presented here.

Statistical Analysis

Sampling weights were used when calculating point estimates in order to account for individual selection probabilities and adjustments for non-response, non-coverage, and poststratification which resulted from the complex survey design used in HHANES. When the appropriate weights are used, the samples are representative of the Mexican origin population in the five southwestern states, the Cuban origin population in Dade County, Florida, and the Puerto Rican origin population in the New York City area.

The complex survey design used in the HHANES tended to increase the variance which would have been obtained through simple random sampling.[12] The complex survey design was accounted for by using an average design effect to adjust the variance calculated under the assumption of simple random sampling. As described by Kovar,[13] the design effect is the ratio of the variance of a statistic from a complex sample to the variance of the same statistic from a simple random sample. The value of the design effect is an indicator of the impact of the complex sample design on the variance.

The average design effect for hypertension was 1.0 for all three Hispanic subgroups. The complex design, therefore, has little effect on the variances and one could consider assuming simple random sampling for these analyses. A t-test was used to compare point estimates. All data analyses were done using programs accessible through SAS.[14]

The direct method was used for age adjustment. The reference population was the civilian noninstitutionalized population of the United States at the midpoint of the NHANES II, March 1, 1978.

Results

Prevalence of hypertension from HHANES is presented by subgroup, sex, and age in Table 1. These estimates represent approximately 775,000 hypertensive Mexican Americans in the southwest, 56,400 hypertensive Cubans in Dade County, Florida, and 78,000 hypertensive Puerto Ricans in the New York City area at the 1983 population levels.

Expected age and sex differences in hypertension were observed for the three Hispanic subgroups. The prevalence of hypertension was higher in older age groups for each of the three Hispanic subgroups. The rates of hypertension were age-adjusted, using the US population in 1978 as a reference (the mid-point of NHANES II). Men had significantly higher age-adjusted prevalence estimates for hypertension compared to women in the Mexican American (95% CI = 0.2, 6.2) and Cuban American (95% CI = 1.4, 12) subgroups. Age-specific comparisons between sexes suggest the same conclusion.

Table 2 presents the distribution of blood pressure levels regardless of medication status, among men and women in the Hispanic subgroups. The results are similar for all three Hispanic subgroups. The great majority of individuals in the HHANES populations have blood pressure measurements in the normal range. Mild diastolic elevation (DBP 90-104) ranges from 2.7 percent to 11.1 percent in the HHANES populations. Isolated systolic hypertension (SBP > = 160) was discovered in a very small portion of the population (less than 1.2 percent).

The distribution of blood pressure levels among hypertensives is presented in Table 3. By far the largest numbers of hypertensives are found in the mild hypertensive category (DBP 90-104), approximately 40 percent. Taken together, those with borderline isolated systolic hypertension (SBP 140-159) and isolated systolic hypertension levels (SBP > = 160) made up over one-third of all the Hispanic hypertensives. Less than 20 percent of all hypertensives (140/90) were controlled by medication.

A number of statistically significant results were observed comparing hypertension rates from HHANES with Whites and Blacks in the general population as measured in NHANES II (1976–80). Hypertension is more prevalent among Whites or Blacks than it is among Mexican Americans, Cuban Americans, or Puerto Ricans (see Table 4). Individual comparisons using the age-adjusted estimates revealed that each of the three Hispanic subgroups had statistically significant lower levels of hypertension than did either Blacks or Whites. Comparisons of age-specific rates suggest the same conclusion.

*Includes those hypertensives who are controlling their blood pressures.
SOURCE: NCHS, HHANES, 1982–84

Results of comparisons of the distribution of blood pressure levels (regardless of medication status) indicate that Whites or Blacks in NHANES II generally had higher levels in each elevated blood pressure category when compared to Hispanics. Whites and Blacks (both sexes) were two or three times more likely to have mildly elevated diastolic blood pressure (DBP 90-104) than each of the Hispanic subgroups. Among White men and women, as found in the JNC 1984 report, 18.4 percent and 10.8 percent, respectively had mildly elevated diastolic blood pressure. Mildly elevated diastolic blood pressure has been found in 20.6 percent and 17.9 percent of Black men and women, respectively. Whites and Blacks were also more likely to have moderately (DBP 105-114) and severely elevated (DBP > = 115) blood pressures, compared to Hispanics.

The proportion of hypertensives (160/95) aware, treated, and controlled is presented by sex and Hispanic subgroup in Table 5. Awareness was high among women, over 95 percent in each of the three groups. Within each Hispanic subgroup, women hypertensives reported having been told about their hypertension more often than men. A substantial portion of Mexican American and Puerto Rican male hypertensives, i.e. 32.1 percent and 21.3 percent, respectively, are unaware of their condition.

Similarly, a larger number of Mexican American and Puerto Rican men were on no medication for their condition, compared to women in those subgroups. Cuban American hypertensive men were more likely to be on medication than hypertensive men in the other two Hispanic subgroups.

Control rates among hypertensives using the 1990 Objectives definition were generally low. With the hypertension threshold at 160/95 and control threshold at 140/90, the proportions of male hypertensives under control were 22.6 percent, 26.1 percent, and 11.9 percent for Mexican Americans, Cuban Americans, and Puerto Ricans, respectively (see Table 5). Higher rates of control were found among hypertensive women as compared to men, except in the Cuban subgroup where the level of control was similar for male and female hypertensives. No group attained the 1990 Objectives of 60 percent controlled.

TABLE 3—Percent of Individual Blood Pressure Readings (systolic and diastolic) around Critical Values for Definition of Hypertension

Diastolic Blood Pressure	Percent	Systolic Blood Pressure	Percent
86	30.8	136	24.6
88	31.7	138	15.4
90	17.5	140	25.4
92	10.8	142	21.4
94	9.1	144	13.3

SOURCE: NCHS, HHANES 1982–84

Using a less stringent threshold for control (160/95), men still fall short of the objective of 60 percent control; 38.4 percent, 50.6 percent, and 19.7 percent of the hypertensive males (160/95) were controlled for Mexican Americans, Cuban Americans, and Puerto Ricans, respectively.

Discussion

The major finding of this study is that the HHANES populations had significantly lower proportions of hypertensives than did Whites or Blacks in NHANES II. This finding is supported by studies showing lower cardiovascular mortality rates among Mexican Americans and Puerto Ricans.[4,15] However, cardiovascular diseases remain a leading cause of morbidity and mortality in these groups and the importance of hypertension should not be underestimated.[16]

Lower rates of hypertension are contrary to the expectations suggested by levels of risk factors for the condition among Hispanics. Considering the generally lower socioeconomic status of Hispanics,[2] the high prevalence of obesity,[17] and the high prevalence of diabetes,[18] we would anticipate hypertension rates to be higher than Whites. A study of risk factors for hypertension using HHANES data may shed light on this problem.

*Hypertension is defined as either >=160/95 or reported currently taking antihypertensive medication.

**Control is defined as a threshold of 140/90.

Previous surveys comparing blood pressure levels of Hispanics with Whites have given inconclusive results. The results of the San Antonio Heart Study, conducted between 1979–82, suggests that Mexican American males had a prevalence of hypertension approximately equal to Whites, and Mexican American females had lower rates than White females.[4] In Orange County, California, Hispanics and non-Hispanics were found to have similar systolic and diastolic blood pressure.[5] The California Hypertension Survey (1978) found that Hispanic men had slightly lower rates of hypertension than White men. Among women, the prevalence of hypertension was higher in Hispanic women than in White women in the younger age groups and somewhat lower in older age groups.[6] The one study of blood pressure among Puerto Ricans was small in scale and nonrepresentative.[7] No study of Cuban American blood pressure has previously been published. The conclusions of these earlier studies which differ from those presented here may be due to the larger and more representative sample selected in HHANES.

The limitations of these data include the facts that: 1) hypertensives controlling their blood pressure without medication are not included in the definition; 2) only the civilian, non-institutionalized population ages 18–74 are included; 3) the sampling universe defined in HHANES does not include all persons of Hispanic origin; and 4) measures were taken on only one occasion. The use of blood pressure measurements on one occasion limits both the definition of hypertension and the "1990's" definition of control. Clinical definitions require more than one elevated measurement and the "1990 Objectives" define long-term control as "at or below 140/90 for two or more years."

The comparison of the prevalence of hypertension among Whites, Blacks, and Hispanics presented here must address the possibility of temporal changes. The NHANES II and HHANES were conducted five years apart. The prevalence of hypertension in the general population has remained relatively stable over the past 20 years.[19] The incidence of hypertension also seems to have been stable for this period as measured in the Framingham study population.[20] Comparisons between the temporally separated NHANES II and HHANES are useful if we reasonably assume the rates among Hispanics have also been stable.

No comparisons of Whites or Blacks with the three Hispanic subgroups were attempted for awareness, treatment, and control status. Direct comparison of HHANES and NHANES II for the status of awareness, treatment, and control of hypertension is inappropriate because of well described secular trends. Over the past decade, awareness of hypertension has increased, more people have begun treatment, and control has improved.[21–23] These important changes were happening during the interval between NHANES II (1976–80) and HHANES (1982–84). To the extent that US Hispanics have participated in the transition, we would expect that awareness, treatment, and control of hypertension also would have improved since the time when NHANES II was conducted.

IOM Conference on Health Status Assessment: Call for Papers

The Institute of Medicine of the National Academy of Sciences has announced a call for papers for its September 1991 conference on Advances in Health Status Assessment. Building on the outcome of two previous conferences (1986 and 1988) this conference will concentrate on the use and usefulness of health status and health-related quality of life measures in clinical practice, especially ambulatory care, and in clinical research that will directly facilitate the application of these measures by practitioners. The following issues are of particular interest, although others will be considered, and empirical research papers are especially invited.

- The use of measures of health status and health-related quality of life as aids in screening, planning patient care, monitoring individual patient outcomes of care, or evaluating quality of care in ambulatory clinical settings;
- Improvements in the definition, reliability, validity, and other methodologic or statistical aspects of health status and outcome measures, as they related to clinical settings.

The deadline for submission of abstracts of at least 2500 words is February 15. Author notification will be on or about April 1, with first drafts due June 1 and final publishable versions due August 1. For further information, contact Kathleen N. Lohr, PhD, or Jo Harris-Wehling, MPA, IOM, NAS, 2101 Constitution Avenue, NW, Washington, DC 20418; (202) 334-2165.

A Note on the Measurement of Hypertension in HHANES

Arline T. Geronimus, ScD, Lisa J. Neidert, PhD, and John Bound, PhD

Abstract: Using data from the HHANES, we found the rates of elevated blood pressure readings on clinical examination to be extremely low for a sample of Mexican American and Puerto Rican women. The prevalence rates were one-fourth to one-fifth the rates found for a comparable sample of White women from NHANESII. These findings are discrepant with the little that is known about hypertension prevalence among Hispanics and with estimates of hypertension prevalence for Mexican Americans and Puerto Ricans drawn from NHANESII. While our HHANES samples women had much lower rates of clinical high blood pressure than Whites, they reported hypertension histories in excess of Whites. Rates of medicine usage among Hispanics were insufficiently large for effective treatment to explain the disparity. The prevalence estimates increased, but the relative discrepancies remained when we altered our sample specifications and clinical high blood pressure measure. A possible explanation for these discrepancies is that few physicians performed the majority of blood pressure readings in our HHANES sample. This may have been statistically inefficient. The discrepancies noted suggest that HHANES may not be a reliable source of information on hypertension among Hispanic women. (*Am J Public Health* 1990; 80:1437–1442.)

Introduction

Hypertension is one of the leading causes of death in the United States. It is an illness that can be easily diagnosed and in the aggregate has responded well to medication. Over the past 20 years, there has been an increase in the proportion of the hypertensive population diagnosed as having hypertension, an increase in the proportion using antihypertensive medicine, and a decrease in the incidence of clinical hypertension.[1] Despite the improvements in the diagnosis, treatment, and control of hypertension in the United States, it remains a persistent health problem, especially for Blacks.[1–3]

Less can be said about the historical or current trends in hypertension for the various Hispanic populations. Most available data have been local area, small-sample studies[4–8] which cannot be generalized to the national population. While Hispanic respondents have often been identified in national health surveys, their numbers were usually too small to analyze well. Often, the definition of the Hispanic population is an aggregation of all Spanish-speaking groups, a practice which ignores the real differences among the various Hispanic groups.[9–11]

With the release of data from the 1982-84 Hispanic Health and Nutrition Examination Survey (HHANES), the potential to apply sophisticated analytical approaches to understanding disease patterns within Hispanic populations is enhanced. HHANES is the only survey that has both large representative samples of members of Hispanic groups within the United States and includes objective measures of health through the examination data, rather than relying only on self-reports. Thus, the validity of the clinical data is critical for the research and policy questions HHANES is intended to address. However, as this paper suggests, there may be problems with the HHANES clinical blood pressure data for women.

Methods

The focus of this analysis is the hypertension data in HHANES. However, to provide a comparison population, information from the National Health and Nutrition Examination Survey, 1976–80 (NHANESII) is also used. Both the NHANESII and HHANES data sets utilized complex, multistage, stratified, clustered samples of defined populations. HHANES differs from NHANESII and previous health interview surveys conducted by the National Center for Health Statistics in that it was not a national probability survey, but a survey of three special subgroups of the population who reside in three geographically distinct regions: Mexican Americans in the southwest United States, Puerto Ricans in the New York area, and Cuban Americans in Miami, Florida. Like NHANESII, the data include an interview and a direct medical examination for a sample of civilian, noninstitutionalized persons 6 months to 74 years of age. (For more details on the sampling procedures used in HHANES and NHANESII, see the NCHS plans for operation.[12,13])

Our ongoing work on the health status of women in their childbearing years led us to the discovery of potential problems with the HHANES blood pressure data. Our sample included all currently menstruating women, who were not pregnant at the time of the survey, and were between the ages of 12 and 54 years. The White and Black members of our sample were drawn from NHANESII while the Puerto Rican and Mexican American sample members were drawn from HHANES. Only respondents who identified themselves as Mexican in the southwest sample or Puerto Rican in the northeast sample were used in the analysis. The resulting sample sizes were 1,700 Mexican Americans, 757 Puerto Ricans, 2,963 Whites, and 509 Blacks. Persons of Hispanic origin have been excluded from the White and Black populations. Due to small numbers, Cuban American women were excluded.

For the HHANES examinations, blood pressure measurements were obtained using procedures recommended by the American Heart Association. For the Black and White populations (NHANESII), three readings were taken (sitting, recumbent, sitting), while for the Mexican American and Puerto Rican populations (HHANES), two readings were taken (both sitting). Additional questions on hypertension history, treatment history and compliance, and current medicine usage were ascertained through the detailed medical history interview. Averages of the available blood pressure

Editor's Note: See also related Different View p 1431 and editorial p 1427.

readings and some of the interview information provide the basis for our determination of hypertension status. The following indicators of hypertension are used in the analysis:

- Respondent has clinical high blood pressure (HBP). In our initial sample clinical HBP was defined as mean arterial pressure (MAP) greater than 105 where MAP = [systolic + (2 × diastolic)]/3.[14,15] As explained below in the text, in later specifications we defined it as systolic ≥ 140 of diastolic ≥ 90.
- Respondent is currently taking antihypertensive medicine.
- Respondent has ever been told by a doctor that she has high blood pressure or hypertension.

It is standard procedure to determine hypertension status on the basis of the first two of these three indicators.[1] Thus, we initially combined them to identify hypertensives. However, when the clinical data appeared questionable, we also looked at the third indicator to learn if the history and clinical data were consistent.

Standard errors are calculated under the assumption that the NHANESII data are simple random samples of the population. The complex sample design implies that these standard errors are almost certainly too small, by a factor that could be as large as $\sqrt{2}$. Initially we attempted to account for the complex samples design using both Taylor series expansion and balanced half sample methods.[16-20] Estimated design effects for the Black, Mexican American, and Puerto Rican samples were often implausibly low (less than 1). These results are consistent with those found by NCHS staff.[21,22] Following NCHS suggested guidelines,[23] which involve averaging design effects across subsamples, did not yield more reasonable results. We thus thought it most reasonable to simply report standard errors without taking into account the complex sample design while warning the reader to interpret results cautiously.

Using the direct method,[24] summary statistics for Blacks, Mexican Americans, and Puerto Ricans are standardized to the age distribution of our White sample.

Results

HHANES Clinical High Blood Pressure Data

Tables 1 and 2 provide selected measures of hypertension according to race and Hispanic ethnicity. Not only do Mexican Americans and Puerto Ricans have the lowest prevalence of elevated high blood pressure readings (clinical HBP), but the overall rate for Mexican American women is only one-third the White rate (1.7 versus 5.1) while the Puerto Rican rate is not even one-fourth of the White rate (1.2 versus 5.1). Even allowing for large design effects, these differences are clearly significant. The rates of clinical HBP also look questionable when they are examined by age (Table 2). Among Puerto Rican women, there are no cases of high blood pressure under the age of 35. Among Mexican American women there are hypertensives in all but the youngest group (<15) but, unlike Black or White women, even at the oldest ages hypertension prevalence does not approach double digits.

TABLE 2—Prevalence of Clinical High Blood Pressure by Race/Ethnicity and Age

	Hispanic		Non-Hispanic	
Age (years)	Mexican American	Puerto Rican	White	Black
<15	0.0	0.0	0.7	0.0
15–24	0.1	0.0	1.1	1.7
25–34	2.0	0.0	3.1	7.3
35–44	3.3	3.1	9.7	22.8

Total[a]	1.7	1.2	5.1	9.2

[a]Standardized to the White non-Hispanic population
SOURCE: HHANES, 1982–1984 and NHANESII, 1976–1980.

The low magnitudes and unusual age patterns of hypertension prevalence we observed in HHANES based on clinical high blood pressure were unanticipated. That both Hispanic populations had prevalence rates that were not simply lower than, but were actually only a fraction of, the White was unexpected. This led us to question whether Mexican American and Puerto Rican women do indeed have extremely low rates of hypertension or whether the clinical high blood pressure data for Puerto Rican and Mexican American women in HHANES were downwardly biased.

To examine the matter further we conducted the following exercises: 1) we compared our findings to those in the literature on high blood pressure among Mexican Americans and Puerto Ricans; 2) we compared the clinical high blood pressure data in HHANES to that reported for the Mexican American and Puerto Rican respondents in NHANESII; 3) we considered other measures of hypertension in HHANES; 4) we checked the sensitivity of our prevalence estimates to our sample specifications and clinical measure of high blood pressure; and 5) we considered the possibility that study effects, specifically physician effects, influenced the HHANES clinical data.

Comparisons with Other Studies

A few recent studies have examined hypertension in the Mexican American and Puerto Rican populations.[4-8] The one Puerto Rican study was of a highly selected sample in the Bronx (participants at a health fair), from which it is difficult to generalize. However, hypertension rates were very high, with the majority of sample members hypertensive. Most studies of Mexican Americans have been local area studies and, thus, cannot be generalized to the US Mexican population. These local area studies have not usually focused

TABLE 1—Selected Measures of Hypertension by Hispanic Ethnicity and Race, Age Standardized to the White Non-Hispanic Population, with Standard Errors

	Clinical HBP				Current Medicine Usage				HBP History				Clinical HBP + Medicine Usage

Percent Hypertensive (Standard Error)	1.7 (.3)	1.2 (.4)	5.1 (.4)	9.2 (1.3)	2.2 (.4)	2.1 (.5)	2.7 (.3)	5.2 (1.0)	13.7 (.8)	17.2 (1.4)	12.8 (.6)	19.3 (1.7)	3.5 (.4)	2.8 (.6)	6.5 (.4)	12.2 (1.4)

SOURCE: Menstruating, non-pregnant women ages 12-54 HHANES, 1982-84 and NHANESII, 1976-80 specifically on women and, when women have been included, the age stratification is not as detailed as in our study. Nevertheless, data from the local area studies indicate that the Mexican Americans do not have extremely low rates of hypertension. For example, both a Laredo, Texas[4] and a Sacramento, California[7] study found rates of hypertension for Mexican Americans to be intermediate between Whites and Blacks, while a study comparing Mexican Americans and non-Hispanic Whites in San Antonio, Texas found them to have roughly comparable rates.[6] Point estimates were slightly lower for Mexican American women compared to non-Hispanic Whites, but this difference was not statistically significant. We were able to simulate a portion of the Laredo, Texas study using the HHANES data. Using the same sample specifications and the same measure of clinical hypertension as used in that study (diastolic $\geq$ 95), we were able to calculate a prevalence estimate for one age group, women 40–49 years. While in the Laredo study the point estimate for this group was 7.9 percent, using HHANES data, ours was only 1.9 percent.

Hispanics in HHANES versus NHANESII

Using the NHANESII data, Table 3 presents several measures of hypertension for Mexican American, Puerto Rican, Black, and White women. It is important to note sample sizes. There are only 35 Puerto Rican women in NHANESII, too few for analysis of a rare event such as hypertension. There are 140 Mexican American women which is much less than what one could find in HHANES, but enough for rough comparisons.

Unlike in HHANES, Hispanic hypertension rates in NHANESII are fairly comparable to those found among White women. The point estimates for Hispanic women in NHANESII are actually higher than those for Whites. Using NHANESII, the ordering of prevalence rates by racial/Hispanic ethnic identification is what one might expect based on the local area studies and what is more generally known about the relative health and socioeconomic status of US Black, Whites, Puerto Ricans and Mexican Americans.[25]

Other Measures of Hypertension in HHANES

HHANES has several indicators of hypertension besides the clinical measure, most prominently self-reported history data. The clinical data and the hypertension history data in HHANES appear discrepant (see Table 1). If Mexican American women had a low prevalence of hypertension, we might expect to see a low prevalence of positive hypertension histories. Mexican American and White women report positive hypertension histories in roughly equal proportions, while Puerto Rican women report a positive hypertension history significantly *more* often. Inspecting the data within age groups, we observed additional anomalies. Examples are (not reported in the tables): among the 27 Puerto Rican women 48 to 50 years of age, 13 (43 percent) report a history of high blood pressure; yet only two currently have an elevated clinical reading and three are taking antihypertensive medicine. Among the 42 Mexican American women in this age interval, 15 (33 percent) report a history of high blood pressure; yet only nine are defined as currently hypertensive (four with clinical high blood pressure and five currently using antihypertensive medication). Some of the "history only" women were probably reporting an experience with a finite hypertensive period such as pregnancy-induced hypertension. However, to explain the entire discrepancy by this fact, one would have to assume that Mexican American and Puerto Rican women are far more prone to such periods than are Black or White women, since discrepancies of this magnitude were not found among Blacks or Whites. Similarly, to infer recall bias explains the entire difference would imply that Hispanics are more likely to misreport than Blacks or Whites, and that both Hispanic groups misreport in the same direction. This seems unlikely and is also unsupported by the Hispanic data in NHANESII. Among Mexican Americans and Puerto Ricans in NHANESII, there is a −0.5 point and a 3.5 point difference, respectively, between the percent reporting a history of hypertension and those with evidence of current hypertension. The differences in the HHANES data are much greater at 10.2 points (Mexican Americans) and 14.4 points (Puerto Ricans).

We also considered the effects relevant secular trends might have on our findings. The NHANESII and HHANES surveys were implemented several years apart. During this time efforts were made to educate the public about the effects of hypertension and the importance of treatment. The secular trends in awareness would lead us to expect to find higher percentages reporting a history of hypertension and higher percentages reporting experience with antihypertensive treatment in HHANES compared to NHANESII, but hypertension prevalence estimated as the combination of elevated readings and medicine usage would not be expected to be lowered dramatically. Comparing the HHANES and NHANESII results, the proportions of self-reported histories did increase between the two surveys, as expected, but hypertension prevalence was lowered far beyond what one might expect. The rate of elevated clinical readings decreased 75 percent for Mexican Americans and 86 percent for Puerto Ricans; the prevalence rate (elevated readings plus medicine usage) decreased 54 percent for Mexican Americans and 68 percent for Puerto Ricans.

Questions are also raised by comparisons of the medicine usage and hypertension prevalence data. If the clinical data are taken at face value, the figures in Table 1 show that 63 percent of hypertensive Mexican American women and 75 percent of hypertensive Puerto Rican women take medicine. The corresponding figure for White women is 42 percent and for Black is 43 percent. These figures suggest that hypertensive Mexican American and Puerto Rican women (women who are members of populations usually described as medically underserved) undergo medical treatment in higher

proportions than hypertensive members of other populations. An alternative explanation for these percentages would be that they are artificially inflated by a downwardly biased denominator, i.e. that the clinical data are inaccurate.

Altering Sample Specifications

We wondered to what degree the estimates we calculated were sensitive to our specific sample specifications and measure of high blood pressure. Consistent with the aims of our larger research program, we had restricted our sample to menstruating women and had used a measure of high blood pressure (MAP) that is commonly used in the obstetric/gynecological literature[26,27], but is not as common in other areas of clinical practice or research.

In Table 4, we report hypertension prevalence estimates (systolic ≥ 140 or diastolic ≥ 90) by age for all Mexican American and Puerto Rican women in HHANES, ages 12–54. Data on medicine usage, history, and a measure that combines clinical and medicine usage data are also reported for these women, as are data for Whites, Blacks and Hispanics in NHANESII. With these changes, we expected rate increases, because MAP is a conservative measure of hypertension that excludes some borderline hypertensives. As expected, the new estimates are higher than those using our previous sample specifications and measure, especially at the older ages where menopausal women have been added. However, the contrasts between clinical hypertension status versus hypertension history remain large. The clinical rates for Puerto Rican and Mexican American women in HHANES remain much lower than the White or Black rates, in each case being no more than one-half the White rate. Again, applying the new specifications to data from NHANESII suggests a different picture from HHANES, suggesting that our initial findings were not simply an artifact of the original specifications.

A Possible Explanation

Great effort was put into quality control when the HHANES data were collected, but our findings raise the question of whether some sort of study effect might explain the low rates of elevated blood pressure readings among examinees. One possibility is the fact that only a few physicians were relied upon to perform the majority of the clinical examinations. This practice has the potential to influence the validity of hypertension data. In general, blood pressure readings have been observed to be subject to variation between examiners.[28,29] This is not to suggest that some physicians' readings are incorrect, but only that there is some expected variation in reporting around "true scores." If there were many physicians evenly distributed across cases, the physician effects would tend to cancel out. However, a reliance on a small number of physicians introduces an extra element of sampling error, one that will not necessarily be accounted for by the calculation of standard errors.[30] As the National Center for Health Statistics has, itself, warned in the past, this practice can seriously jeopardize the validity of a survey.[29]

Table 5 shows the distribution of physicians across the Mexican American and Puerto Rican surveys in our initial sample. Each survey used only four physicians. The distribution of these examiners is uneven, particularly in the Mexican American sample. In the Mexican American survey, Doctors 501 and 502 examined 96 percent of the cases. In the Puerto Rican sample, the examinations are spread across three doctors who, as a group, performed 98.7 percent of the readings.

As shown in the Appendix, we performed sample calculations to estimate the potential statistical inefficiency that might have resulted from the usage of so few examining physicians in HHANES (effectively two for the Mexican American sample and three for the Puerto Rican). The magnitude of the inefficiency produced by using so few physicians depends on both the ratio of the sample size to the number of physicians and on the magnitude of the physician effects. Our estimates suggest that standard errors could have been enlarged three-fold for Puerto Ricans and six-fold for Mexican Americans by the employment of so few physicians.

We conclude from these sample calculations that there appears to be enough variability between examining physicians in the proportion they are likely to diagnose as hypertensive that using only two or three physicians has the potential to reduce substantially the reliability of the survey. However, we present this only as one possible explanation for the low prevalence estimates we found. The data do not permit us to test or rule out other possible systematic biases. We cannot know how likely the physician effects explanation is relative to alternative explanations based on other potential sources of systematic bias.

Conclusions

The several features of the HHANES hypertension data for women we have described suggest that it is wise to be wary of these data and exercise caution when interpreting them. The prevalence of elevated readings at the HHANES examination is low compared to analyses using other data. These examination data appear more discrepant with the history data than is true in NHANESII or that can be accounted for reasonably by recall bias. The validity of the HHANES clinical high blood pressure data may be threatened by the reliance on only a few examining physicians.

Hispanic groups in the US are understudied populations. Given this lack of benchmark data to which we would compare the HHANES data under ideal circumstances, we cannot conclude definitively that the low rates of elevated blood pressure readings estimated for reproductive-age women in HHANES are invalid. However, careful review of the available information reveals inconsistencies that suggest to us that hypertension prevalence estimates based on the HHANES examination data are downwardly biased.

APPENDIX

The magnitude of the inefficiency due to the reliance on few examining physicians depends on both the ratio of the sample size to the number of doctors and on the magnitude of the doctor effects. In particular, imagine that n doctors each examine m respondents. Also, let the true population proportion with hypertension be π, while the probability that the i_{th} doctor identifies a person as hypertensive is π_i. While we might assume that

$$E_i(\pi_i) = \pi,$$

the fact that there are doctor effects implies that, in general, $\pi_i \neq \pi$. A natural measure of the magnitude of these effects is just the variance of the π_i's,

$$\sigma^2_{\pi_i} = E_i(\pi_i - \pi)^2.$$

Were it not for the doctor effects the sampling variance of p, the proportion of respondents with hypertension, on a sample of size $N = mn$ would just be

$$\frac{\pi(1 - \pi)}{N}.$$

Doctor effects add an extra component to this variance. With doctor effects the variance will be

$$\frac{E_i[\pi_i(1 - \pi_i)]}{N} + \frac{\sigma^2_{\pi_i}}{n}.$$

Thus the efficiency of the survey design relative to that of a simple random sample is just:

$$\frac{\dfrac{E_i[\pi_i(1 - \pi_i)]}{N} + \dfrac{\sigma^2_{\pi_i}}{n}}{\dfrac{\pi(1 - \pi)}{N}}$$

Note if either the number of doctors used, n, is larger or doctor variability, $\sigma^2_{\pi_i}$ is small the above expression approximates 1 implying that in these circumstances the inefficiency is small.

To evaluate this expression we need an estimate of $E_i[\pi_i(1 - \pi_i)]$ and $\sigma^2_{\pi_i}$. With effectively only two doctors in the Mexican and three in the Puerto Rican samples there are too few doctors to allow a reasonable estimate of $\sigma^2_{\pi_i}$. What we can do, though, is use the sample of Whites in NHANESII to calculate sample analogies for the above expressions. From these we can estimate the impact that using only two or three doctors would have on the efficiency of the NHANESII survey.

In the NHANESII survey the 2,963 White women were surveyed by a total of 13 doctors. The sample variance,

$$S^2_{\pi_i} = \frac{\sum_i(p_i - \bar{p}_i)^2}{12}$$

is .00230. The sample variance reflects both systemic differences between the doctors and sampling variability. To get an estimate of $\sigma^2_{\pi_i}$ we need to subtract off from $S^2_{\pi_i}$ an estimate of the sampling variability. This we can estimate as

$$\frac{\sum_i\left[\dfrac{p_i(1 - p_i)}{m_i}\right]}{n}$$

= .00046. Thus a calculation gives us an estimated $\sigma^2_{\pi_i}$ of .00230 − .00046 = .00184. To estimate $E_i[\pi(1 - \pi)]$ we simply use

$$\frac{\sum_i p_i(1 - p_i)}{12}$$

= .04580.

Now suppose that we were to redo the NHANESII survey using only two doctors, each of whom tests 800 respondents (similar to the distribution in the Mexican sample). Evaluating the above formula implies that the efficiency of the random sample is 35 times that of the sample using only two doctors. In other words, the standard errors are almost six times what they would have been with random sampling. Redoing the calculation assuming that three doctors each do 250 cases (similar to the distribution in the Puerto Rican sample), we find that a random sample with the number of respondents would be roughly 11 times as efficient or the standard errors are more than three times as large as they would be with a random sample. We conclude from these samples calculations that there appears to be enough variability between physicians in the proportion they are likely to diagnose as hypertensive that relying on only two physicians to examine the Mexican American women and only three for the Puerto Rican women has the potential to reduce substantially the survey's reliability.

Fruit and Vegetables in the American Diet: Data from the NHANES II Survey

Blossom H. Patterson, MA, Gladys Block, PhD, William F. Rosenberger, MPhil,
David Pee, MPhil, and Lisa L. Kahle, BA

Abstract: Twenty-four hour dietary recall data from the Second National Health and Nutrition Examination Survey (1976–80) were used to estimate the numbers of servings of fruit and vegetables consumed by Black and White adults, to examine the types of servings (e.g., potatoes, garden vegetables, fruit, and juice), and to estimate the mean intake of calories, fat, dietary fiber, and vitamins A and C by number of servings. An estimated 45 percent of the population had no servings of fruit or juice and 22 percent had no servings of a vegetable on the recall day. Only 27 percent consumed the three or more servings of vegetables and 29 percent had the two or more servings of fruit recommended by the US Departments of Agriculture and of Health and Human Services; 9 percent had both. Consumption was lower among Blacks than Whites. The choice of vegetables lacked variety. Diets including at least three servings of vegetables and two servings of fruit contained about 17 grams of dietary fiber. Although caloric and fat intake increased with increasing servings of fruit and vegetables, the percent of calories from fat remained relatively constant. Although these data are 10 years old, more recent surveys have shown similar results. The discrepancy between dietary guidelines and the actual diet suggests a need for extensive public education. *(Am J Public Health* 1990; 80:1443–1449)

Introduction

In a recent article,[1] it was found that a large proportion of the adult United States population eats no vegetables (0.17) or fruit (0.41) on any given day. The Surgeon General's Report on Nutrition and Health[2] recommends increasing consumption of vegetables and fruit. Based on a comprehensive literature review, the National Academy of Sciences (NAS) concluded that diet influences the risk of several major chronic diseases and recommended eating five or more daily servings of a combination of vegetables and fruit, especially green and yellow vegetables and citrus fruit.[3] The US Department of Agriculture (USDA) and the Department of Health and Human Services (DHHS) recommend as part of their food guidance system that the daily diet include two to three servings of fruit and three to five servings of vegetables.[4,5] These specific recommendations are in the context of general recommendations for a diet that meets nutrient requirements, does not include excessive amounts of fat (in particular saturated fats), and is consistent with maintaining desirable weight. It is important therefore to determine what relation increased fruit and vegetable consumption might have, not only to intake of obviously related nutrients such as vitamins A and C but also to fat intake and maintenance of appropriate body weight. In the NHANES II data, collected between 1976 and 1980, it is possible to examine these relationships in self-selected diets that were actually consumed during a 24-hour period by a representative sample of US adults.

The article mentioned above[1] described the proportions of the US population that consumed any amount of a given food, however large or small; no attempt was made to determine the number of servings consumed. In the present inquiry we estimate the number of servings consumed, taking portion size into account. We also examine the intake of calories, fat, fiber, and vitamins A and C in the diets of persons consuming various numbers of servings of fruit and vegetables. While it is obvious that intake of vitamins A and C would increase with increasing numbers of servings, the relative contribution of fruit versus vegetables is not well known, nor is the nutrient intake actually achieved in self-selected diets. Similarly, the dietary fiber intake contained in diets including multiple servings of fruit and vegetables may be inadequately appreciated by the general public.

Methods

The NHANES II survey was conducted by the National Center for Health Statistics between 1976 and 1980.[6] A highly stratified multi-stage probability design was used to obtain a representative sample of the civilian noninstitutionalized population, ages six months to 74 years; we report on 10,313 White and 1,335 Black adults ages 19 to 74. We excluded other races because of small numbers, as well as imputed, unreliable, or surrogate data. Results are based on weighted data, permitting inference about the total Black and White noninstitutionalized US population.[7] Group means and standard errors were calculated using software appropriate for complex sample survey data.[8] Standard errors are frequently large for Blacks, due to their small number in the survey. Therefore, results for Blacks should be viewed with caution. Conversely, standard errors for Whites are small due to the very large sample size, so that small differences in intake, while not biologically meaningful, could be statistically significant.

Dietary interviews were conducted by interviewers with a knowledge of food preparation and nutrient composition. A measure of portion size was obtained using three-dimensional food models, as well as dishes and glassware of various sizes. Subjects were asked to report all food and drink consumed in the 24-hour period before the interview day. Almost all recall days were weekdays. Food codes, food weight, and nutrient values were based on data from the USDA, industry, and other sources.[9] The coding of these foods has been described elsewhere.[10] Based on reported portion sizes, the number of grams consumed was calculated and included on the 24-hour recall tape[11] for each food reported by each respondent.

Address reprint requests to Blossom H. Patterson, MA, Clinical and Diagnostic Trials Section, Biometry Branch, Division of Cancer Prevention and Control, National Cancer Institute, Executive Plaza North, Rm 344, Bethesda, MD 20892. Dr. Block is also with that Section at NCI; the other co-authors are with Information Management Services, Inc., Silver Spring, MD. This paper, submitted to the Journal August 3, 1989, was revised and accepted for publication May 10, 1990.

We converted the number of grams reported for each fruit and vegetable into a number of servings as follows. We used as a guide suggested serving sizes given by a food guidance system developed to help implement the USDA/DHHS dietary guidelines.[5] For fruits, a serving is defined as an average piece of whole fruit or six ounces of fruit juice, and for vegetables, one-half cup, cooked or raw. An examination of a sample of actual food records showed that some reported amounts of fruit or vegetables, such as a slice of onion on a hamburger, or lemon juice added to tea, were too small to be considered a serving, while others were so large that they should be considered as more than a single serving. We chose a lower limit of one ounce (30 grams) for any serving of a fruit or vegetable, and two ounces (62 grams) for fruit juice. Small lower limits on a single serving were chosen so as not to eliminate portions consumed by persons with small appetites. This choice may result in some overestimation of the proportions eating one or more servings on the recall day. We chose an upper limit for a single serving so that a large portion (eaten on a single occasion) would be treated as more than a single serving. A single portion of a fruit or vegetable was considered to be at most two servings so as not to overestimate the number of servings of big eaters. Juice consumed on a single eating occasion was considered (at most) three servings.

In order to convert a large portion of whole fruit or vegetables into two servings, we determined a representative or "typical" number of grams in a half cup serving of vegetables, and the weight of an "average" piece of fruit, using weights given for the most popular[1] vegetables and fruits in Agriculture Handbook No. 456.[12] A half cup serving of many vegetables weights about 75 grams, and many whole fruits weigh roughly 120 grams. We defined as two servings any portion of vegetables (except salad) weighing 150 grams or more, and any portion of fruit (excluding fruit juice) weighing 240 grams or more. For fruit juice, individuals consuming between 12 and 18 ounces (372 to 557 grams) were given credit for two servings of fruit, and those consuming 18 or more ounces (558 or more grams) were given credit for three servings. An individual eating a green salad on a single occasion was given credit for a single serving rather than for multiple servings corresponding to each ingredient. Thus individuals could be credited with a maximum of one salad per eating occasion, or a maximum of the four different occasions per day coded in the survey.

Individual foods included in each food category are given elsewhere.[1] Vegetables include potatoes, dried peas and beans (e.g., black-eyed peas, kidney beans), green salad (primarily lettuce and raw tomatoes), as well as all other vegetables not falling into one of these categories. This last group is designated "garden vegetables" and includes, for example, green beans, corn, and broccoli. "Fruit" refers to whole fruit and fruit juice. In this article, fruit juices include citrus and other natural fruit juices, but exclude both fortified and non-fortified fruit "drinks." A list is available from the authors on request.

We report mean nutrient intake by number of servings (0, 1, 2, 3 or more) of fruit cross-classified by number of servings of vegetables. Nutrient intake was calculated by the National Center for Health Statistics, using USDA nutrient data, updated 1980. Because consumption of fruit and vegetables is associated with age, sex, and race,[1] we controlled for these factors in each cell of the cross-classification tables using a method equivalent to direct standardization. This method for finding means and the corresponding variance estimates, adjusted for age, race, and sex, is given in the Appendix. The method uses regression coefficients to obtain estimates of means.

Results

Because the NHANES II data were collected before the recommendations above were issued, they do not reflect their impact; rather the guidelines are used as a standard against which to describe the diet. In the spirit of both the USDA/DHHS and NAS guidelines, we define three or more servings of vegetables and two or more servings of fruit as meeting the vegetable and fruit guidelines, respectively. The proportions meeting these guidelines are shockingly small (Table 1). On the recall day, 27 percent met the vegetable guidelines and 29 percent met the fruit guidelines, while only 9 percent met both. In general, proportions were highest among older Whites but, even in this group, fewer than one-third ate the recommended servings of vegetables, and fewer than half ate the recommended servings of fruit. More men had adequate numbers of servings of vegetables than did women; the opposite was true for fruit. About two-thirds as many Blacks as Whites met these guidelines. Only about 5 percent of Black women and 7 percent of Black men consumed the recommended numbers of both fruit and vegetable servings.

Eleven percent ate neither fruit nor vegetables on the recall day, 45 percent had no servings of fruit, and 22 percent had no servings of a vegetable (Table 2). In contrast to the five or more servings of fruit and vegetables recommended, zero or one serving might be considered clearly inadequate. Thirty-five percent of Black adults and 27 percent of White adults had at most one serving of a food in the fruit/vegetable food group (data available from author on request).

Mean numbers of servings of fruit (1.08, SE = .03) and vegetables (1.77, SE = .02) were far below recommended levels and were lower for Blacks than for Whites (data available from author on request). Mean vegetable intake was

somewhat higher for males than females; the opposite was true for fruit and juice. The mean number of servings of garden vegetables, a group including the green and yellow vegetables emphasized by the NAS guidelines, was only 0.65 (SE = .01).

At least one serving of garden vegetables was eaten by 43 percent of the adult population, and there were no notable differences by race or sex (Table 3). Potatoes and salad were more popular among Whites than Blacks. Proportions eating fried potatoes declined with age, while those consuming non-fried potatoes increased (data available on request to author). Dried peas and beans, good sources of fiber, were eaten by only about 10 percent of the population.

About half the population consumed no servings or only one serving of a vegetable (Figure 1). Among those who reported only one serving of a vegetable, salad was the most popular, reported by 39 percent. Twenty-nine percent consumed a serving of potatoes as their only vegetable, and over half of these servings of potatoes were fried. Among those reporting two servings of a vegetable, some did not achieve variety: 9 percent had two servings of potatoes, 7 percent reported two servings of salad, and 5 percent ate two servings of dried peas and beans.

Only slightly more than half of the population (55 percent) had at least one serving of fruit or fruit juice. Of these, 27 percent had juice only, and 45 percent had whole fruit only (data available on request to author).

Table 4 shows average intake of dietary fiber, vitamin A, and vitamin C among persons consuming various numbers of servings of fruit and vegetables. These nutrient levels represent dietary intake from all food sources, but exclude vitamin supplements. Persons who consumed neither fruit nor vegetables had, on average, only 5.6 grams of fiber in their diet on the recall day, or about one-fourth of the 20–30 grams recommended by the National Cancer Institute.[13] The amount of fiber in these self-selected diets increased with the total number of servings of fruit and vegetables consumed, and this increase was similar for both fruit and vegetables. A total of five servings of a combination of fruit and vegetables was associated with an intake of approximately 17 grams of fiber. The recommended level of fiber intake was achieved only by those who had three or more servings of *both* fruit and vegetables, a group representing only 4 percent of the US adult population.

In the United States, it is estimated that the usual foods available to consumers provide about half of the total vitamin A activity in the diet as provitamin A carotenoids, found in plant products, and the other half as retinol.[14] Among those eating both fruit and vegetables, the US Recommended Daily Allowance (RDA) of 5000 IUs of vitamin A was attained only by those having at least two servings, while five servings of a combination of fruit and vegetables were associated with mean vitamin A intake of about 8000 IUs. If either vegetables or fruit were eaten to the exclusion of the other (true of over half the population), the US RDA was reached only among those having three or more servings.

For vitamin C, fruit and vegetables represent the primary source in the US diet,[10] and Table 4 shows that fruit in particular is associated with higher intake. Among those consuming no fruit, the US RDA of 60mg was attained only by those who had three or more servings of vegetables. This is notable in view of the fact that 45 percent of the US population consumed no servings of fruit on the day of the survey.

Table 5 shows caloric and fat intake by servings of fruit and vegetables. Caloric intake increased as numbers of servings of either food increased. However, the additional calories were not due to the fruit or vegetables alone, as fat intake also increased substantially. This is presumably due in part to fats such as butter and margarine added to potatoes and other vegetables and to oils in salad dressings; people who eat more servings of fruit and vegetables may also eat more food in general. The increase in dietary fat intake associated with increased servings of vegetables was greater than that associated with increased servings of fruit (data available on request to author). Those who ate no fruit and three or more servings of vegetables had an average of 95 grams of fat in their diets, while those who ate three servings of fruit and no vegetables had 78 grams.

*All vegetables except potatoes, salad, and dried peas and beans. Examples are green beans, carrots, and corn.

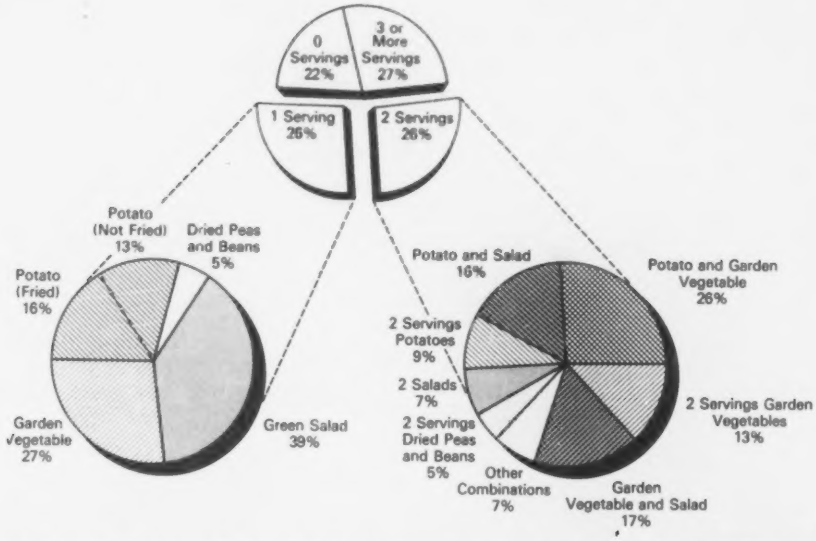

FIGURE 1—The top pie chart shows the percentages of individuals who consumed zero, one, two, or three or more servings of vegetables on the recall day. Percentages are estimates based on data from NHANES II, 1976–80. The lower left pie chart displays the type of vegetable consumed by those who consumed only one serving of a vegetable. The pie chart on the lower right displays the types of vegetables consumed by those who had exactly two servings of a vegetable. The category "garden vegetables" includes all vegetables except potatoes, salad, dried peas and beans. Examples are green beans, carrots, and corn.

When we express fat as a percent of calories, there was a small increase with increasing vegetable intake, approximately two percentage points from the lowest to the highest serving category. In contrast, with increasing fruit consumption, the percent of calories from fat fell approximately five percentage points from the lowest to the highest consumption category. Percent of calories from saturated fat behaved similarly, reaching its highest value among those who consumed no fruit and two or more vegetables, and its lowest value among those who consumed three or more servings of fruit and no vegetables (data available from authors on request).

Although the percent of calories from fat increased slightly with increasing vegetable consumption, this was associated with an increase in the ratio of polyunsaturated fats to saturated fats (P/S ratio), the direction recommended by the American Heart Association[15] (data available from authors on request). This may reflect the use of unsaturated oil in salad dressings.

Despite the increase in caloric intake and dietary fat with increasing numbers of servings of fruit and vegetables, there was no associated increase in obesity (data available from authors on request). A commonly used measure of obesity, the Quetelet Index (weight(kg)/height(m)^2) was relatively constant across all serving categories, ranging from 24.9 (SE = .27) to 25.6 (SE = .18). This may reflect differences in energy expenditure associated with higher caloric levels.

Discussion

"In this land of plenty millions of Americans aren't eating wisely. Not because they haven't enough to eat, but because they eat too many of the wrong things or too little of the right,"[17] according to the USDA. Based on 24-hour recall data, we found that 91 percent of the adult US population did not meet the USDA/DHHS recommendation that two to

three servings of fruit and three to five servings of vegetables be eaten daily.

Our method of defining a serving in terms of the number of grams eaten at any given meal, as opposed to the total number of grams consumed during the entire 24-hour period, may have resulted in some bias in the estimation of number of servings. Small portions (weighing less than an ounce) might sum to a serving over the course of a day, resulting in an underestimation. This bias is probably minimal because of the small lower limits (one ounce of fruit or vegetable) used in the estimation. Conversely, these small limits might result in an overestimation of the number of servings; our lower limit is equivalent to less than half of a serving as defined by the USDA. The second bias is likely larger than the first and, if so, the results presented in this article are unduly optimistic.

While a single day's food record cannot be used to characterize an individual's usual diet, 24-hour recall data can provide estimates of group means.[7] Our finding that 11 percent had no servings of either fruit or vegetables on the recall day is in close agreement with data from the NHANES II food frequency questionnaire in which 12 percent reported that they eat fruit and vegetables less frequently than daily, and with 24-hour recall data from the Nationwide Food Consumption Survey (NFCS), conducted by the USDA in 1977–78, in which 10 percent of women and 8 percent of men ages 19–50 reported eating no fruit or vegetables on the recall day.[18]

A comparison of 24-hour dietary recall data among adults ages 19–50 from the NFCS and from the 1985 and 1986 Continuing Survey of Food Intakes (CSFII),[19–21] also conducted by the USDA, suggests that there has been little change in the percentages using these foods. The proportion of men reporting eating any vegetables on the recall day decreased from 89 to 85 percent between 1977 and 1985, while the proportion reporting fruit consumption was virtually unchanged: 44 percent in 1977 and 43 percent in 1985. For women, changes were also minimal: in 1977, on the recall day, 84 percent reported eating a vegetable, compared to 83 percent in 1985; 50 percent reported eating fruit in 1977 and 47 percent in 1985. CSFII data for women in 1986 were similar. A study of food consumption trends based on NFCS and CSFII data reported that proportions of women using green and yellow vegetables and "lower-fiber" vegetables such as lettuce and tomatoes increased slightly during this period, while proportions using "higher-fiber" vegetables such as corn, green peas, and cooked cabbage decreased.[22] While data from the USDA surveys are directly comparable, these surveys differ somewhat from the NHANES II survey in sampling and in data collection methods. Further, the USDA vegetable group is slightly more comprehensive than ours, and their fruit group excludes some citrus fruit juices, such as lemonade, that were included in our study. Recent promotion of dietary fiber may have produced some increase in the consumption of fruit and vegetables, but is unlikely to have resulted in changes of the magnitude needed to meet the guidelines.

Results of a small survey (298 adults selected by random digit dialing) conducted in two counties in California in 1987[23] were similar to our findings. Fifty-two percent reported that they had eaten one or more fresh fruits on the previous day*; we found that 39 percent ate whole fruit on the recall day. In the California survey, 42 percent reported eating green salad and 67 percent reported eating one or more vegetables on the recall day. In our data, 37 percent had a salad and 43 percent had at least one serving of a garden vegetable on the recall day.

Dietary guidelines have emphasized the importance of a balanced and varied diet. Diets that include either no servings or very few servings of fruit and vegetables lack both balance and variety. We found that almost 50 percent of the population had at most a single serving of a vegetable; even among those who had two servings of a vegetable on the recall day, 21 percent had two servings of the same vegetable (other than a garden vegetable). For fruit and fruit juice, about three-fourths had at most a single serving.

Studies that have assessed health benefits from vegetable consumption found them primarily for garden vegetables.[24-26] We found that less than half the population had a garden vegetable on the recall day.

As in the paper on food choices,[1] we found that consumption of fruit and vegetables (with the exception of garden vegetables) was lower among Blacks than Whites, even when income was taken into account (data available on request to authors). Not only did fewer Blacks than Whites meet the guidelines, but larger proportions had at most a single serving on the recall day.

Consumption of the recommended five servings of fruit and vegetables is consistent with a nutritionally adequate diet as well as with the health recommendations cited above. For example, diets including multiple servings of these foods provide substantial amounts of dietary fiber and vitamins A and C. While caloric intake increases with the numbers of servings of both fruit and vegetables, this increase is not associated with greater obesity. As more servings of vegetables are eaten, more grams of fat are consumed, but the P/S ratio also rises.

---

*Data provided by S. B. Foerster, personal communication.

The fact that fruit and vegetables are important sources of dietary fiber may not be well understood by the general public. In our data, a diet that included five servings of fruit and vegetables provided approximately 17 grams of fiber; at this level, the addition of two slices of whole grain bread would bring the total to 20 or more grams. Nutrition education campaigns might well emphasize that consumption of the recommended five-a-day is important in achieving the dietary fiber goals, as well as in increasing micronutrient intake.

Evidence has been accumulating on the relation of fruit and vegetable consumption to health, as is reflected in the NAS recommendations to increase consumption of these foods. Numerous studies suggest that we can help prevent several types of cancer by increasing our fruit and vegetable consumption.[24-26] However, the discrepancy between the America diet and the fruit and vegetable guidelines, as shown in a one day recall, is so enormous as to call into question the societal commitment to these guidelines. The public is either unaware of the likely benefits of including these foods in the daily diet or, although aware, is unwilling or cannot afford to follow the guidelines.

Fruit and vegetable consumption has never been the object of a national campaign. A recent editorial in this Journal called for "the most vigorous, collaborative nutrition campaign ever launched"[27] to make the public aware of the connection between food intake and health outcome. Any such campaign should take into account the fruits and vegetables most frequently eaten, encouraging increased consumption of those already relatively popular, and targeting demographic groups where consumption is particularly low. In addition to public education, societal commitment might include actions to improve the affordability of many fruits and vegetables and to increase the numbers of servings obtainable through school lunches, meals on wheels, and other food programs, as well as industry actions to promote increased consumption of these foods.

ACKNOWLEDGMENT

We wish to thank Dr. Susan B. Foerster for sharing with us results of the California Two-County Survey.

APPENDIX

We define K indicator (dummy) variables for the K + 1 cells in our classification (K = 15 for the 4 x 4 cross-classification of numbers of servings of fruits and vegetables.) The remaining P - K variables, $X_{K+1}, \ldots, X_p$, represent indicator variables for the categories into which the adjustment variables have been divided (in our case, the three age, two race, and two sex categories generate four additional dummy variables). The continuous variable for which we are adjusting is denoted Y_k, $k = 1, \ldots, K$ (for example, Y_k might be number of calories consumed by those in the k^th cell). Then the adjusted mean for the k^th cell, $k = 1, \ldots, K$, is given by the following regression model:

$$\bar{Y}_k = b_0 + b_k + b_{K+1}\bar{X}_{K+1} + \ldots + b_P\bar{X}_P$$

and the adjusted mean for the $(K + 1)^{th}$ cell is given by

$$\bar{Y}_{K+1} = b_0 + b_{K+1}\bar{X}_{K+1} + \ldots + b_P\bar{X}_P$$

where $\bar{X}_{K+1} \ldots \bar{X}_P$ are means for the whole sample, or, in our case, simply the proportion (in the population) in each age, sex, or race category. A simple interpretation can be given to the adjusted means. The adjusted mean for the k^{th} cell is the mean that would have been generated by the data if the population in the k^{th} cell had the same distribution (with respect to the race, sex, and age categories) as the entire population.

The estimated variance of the adjusted mean can be found by using the estimated variances and covariances of the b's, obtained from the SURREGR procedure,[8] software that takes into account the complex sampling design and the sampling weights.

Executive Women and Health: Perceptions and Practices

JUDITH H. LAROSA, PHD, RN

Abstract: The purpose of this study was to obtain a socioeconomic/health profile of a select group of executive women, to understand more about their personal and professional lives, and to examine how these factors relate to their overall health. The data were obtained from a self-administered 73-item questionnaire that was mailed during spring 1987 to the 1,000 members of a professional executive women's organization with 15 chapters across the United States. Findings suggest that the women in executive positions do not necessarily compromise their health. In comparison with a group of age/gender/education matched working women, the overall wellness and risk assessment scores were remarkably similar. The study group, however, reported greater life satisfaction, stronger social support, and excellent health status; the overwhelming majority was satisfied with their personal and professional lives and believed that they were in control of both. This perception, coupled with the relatively high wellness scores, suggests that on average this group of executives may be in better health than had been predicted as women rose to executive positions within organizations. (*Am J Public Health* 1990; 80:1450–1454.)

Introduction

The role of women has changed—both inside and outside the home. Since the beginning of the twentieth century, many women have moved from the traditional rural culture of child-rearing and farm work to the modern urban culture of nannies and executive boardrooms.

Although the move from farm to city and from home to office has been evolving since the early 1900s, it was during World War II that the major and more permanent change occurred. In 1890, women constituted 18 percent of labor force participation, by 1945 that number had risen to 36 percent, and in 1989, women represented 54 percent of the labor force participation.[1,2]

During World War II, as throughout history, women took on the work responsibilities vacated by men who left home and jobs to fight wars. Unlike the aftermath of previous wars, however, American women did not follow historical precedent and return home to their traditional responsibilities. They continued to work outside the home and over time began to take on occupations previously held by men—medicine, the law, engineering, politics, and others. Gradually they began to take on the power and responsibilities associated with these occupations. In many cases, women added these outside responsibilities to the ones they already had at home—managing the children and the household.

Yet, little attention has been focused on the impact of these changes. Studies are only just now emerging that begin to examine the complex nature of the home/work/health relationships on working women. Some investigators have suggested that functioning in different roles poses health problems for working women,[3–5] while others have suggested that it is beneficial.[6–8] Some have suggested that a critical factor in these relationships is the perception that the woman holds about her life situation.

Prior health studies focused primarily on women in blue-collar occupations, or on women in white-collar occupations who worked at relatively low to mid-level positions.[3–24] Existing studies of executive women usually do not include health data.[25,26] Indeed, only three studies were identified that focused on the health of women in executive positions—either in very large companies or in the federal government.[27–29] The purpose of this study, therefore, was to obtain a socioeconomic/health profile of a select group of executive women, to understand more about their personal and professional lives, and to examine how these factors relate to their overall health.

Methods

The data were obtained from a self-administered questionnaire that was mailed during spring 1987 to the 1,000 members of a professional executive women's organization with 15 chapters across the United States. Entry into the organization is by invitation only and is based on criteria that insists on each member having "substantial influence in her field . . . regardless of title." The organization criteria also states that "there are many influential and powerful women outside large organizations, thus the size of the organization should not be considered as an important criterion." Occupations include chief executive officers, lawyers and judges, physicians and scientists, administrators, politicians, the clergy, artists, and writers. The majority, 54.8 percent, listed their title as executive. The mean income of the respondents was $133,000 per annum; median income was $96,000. The income distribution was positively skewed. The income levels ranged from no income for a Roman catholic nun who was a hospital administrator to several chief executive officers who reported over $3 million in salary per annum. Because of the wide range of incomes, further analyses of income against other key variables are underway.

The questionnaire consisted of 73 items in four major categories—sociodemographic, general health, job satisfaction, and home/work/health relationships. Sociodemographic items were based on those used in the National Health and Nutrition Examination Surveys and National Health Interview Surveys.[30,31] Participants were also asked job-related questions and queried about who bears the major responsibility for making major financial decisions and arranging child care.

The general health section consisted of the 1984 32-item[*] Centers for Disease Control Health Risk Appraisal (CDC HRA) with the exception of one item reflecting exposure to

Dr. LaRosa is also with the Department of Health Education, University of Maryland, College Park. This paper, submitted to the Journal February 20, 1990, was revised and accepted for publication April 6, 1990.

[*] One question was dropped from the original questionnaire at the request of the organization's board. The question was considered offensive and board members felt that such a question would seriously impair the willingness of members to respond. The excluded question was "How many of the following do you usually do? Hitch-hike or pick up hitch-hikers? Carry a gun or knife for protection? Keep a gun at home for protection? Criticize or argue with strangers? Live or work in a high crime area? Seek entertainment at night in high-crime areas or bars?

violence.[32] This instrument was used for two reasons. In addition to providing an assessment of the individual's perception of her health status, the CDC HRA also provided a limited assessment of the respondent's level of personal satisfaction—an important psychosocial variable previously shown to be related to the development of disease.[9–11]

The job satisfaction section consisted of two scales developed by Karasek and colleagues—a five-item job satisfaction scale and a nine-item decision latitude scale.[33–37] These variables were added because professional satisfaction and perception of job mastery are believed to be related to health.[4,9–11,33–37]

Perceptions about control over their lives and the impact of their personal and professional lives on physical health and mental well-being were examined using five questions developed by the investigator. Finally, two open-ended questions were included at the end of the questionnaire for the respondents to add comments on their personal and professional lives and their health, and to reflect on the study. Analyses of the responses to these questions are not included in this paper; they will be the subject of a future analysis.

After a three-phase mailing, designed to maximize the response rate, 66 percent (660/1,000) of the members had responded. Of those 660, 590 cases (59 percent of the total) were complete and usable; 545 of the cases represented executives who were employed full-time. They are the focus of this paper.

Complete data for comparing respondents and nonrespondents were available on only two factors: education and marital status. No differences were found between the two groups on these factors. While differences may have existed, other demographic factors such as age, number of years married, spouse education and income, level of personal and professional satisfaction, and the entry criteria for membership in the organization suggest that this particular population of executive women is fairly homogeneous. The assumption that the respondents and nonrespondents are similar seems reasonable.

Results

The 545 respondents were predominantly White, middle-aged, well-educated, well-paid executives. The majority were married and had an average of two children. Almost 19 percent of the children were 18 years of age or younger. The majority of the spouses, like their wives, were well-educated executives. Table 1 summarizes the selected demographic findings and job characteristics.

Although the majority of the couples had equally well-paying, executive positions, the distribution of jobs at home was not as equitable. While the responsibility for making major financial decisions was a shared responsibility between the partners, the responsibility for arranging child care usually fell to the woman. Seventy-three percent of the respondents reported arranging child care 75 percent or more of the time.

Over half the respondents have had at least two job changes in the past 10 years, usually representing an advancement. While the majority of the respondents worked for a firm other than their own, 28 percent owned their own company. The majority reported high levels of job satisfaction (median equaled 90 on a scale of 0 to 100) and decision latitude (median equaled 86 on a scale of 0 to 100)—indicating an ability to make autonomous decisions regarding their work direction and pace.

TABLE 1—Profile of 545 Full-Time Women Executives

Factors		
Age (years) (Mean/Median)	48.7/48.0 years	
Race (% White)	90.1	
Education (% ≥ Masters)	57.0	
Spouses' Education (% ≥ Masters)	66.1	
Married (%)	59.5	
Married (years)	20.0	
Children (% with)	73.0	
Children (Average Number)	2.0	
Children (% with ≤ 18 years of age)	19.0	
Annual Personal Income (Mean/Median)	$133,785/$96,000	
Spouse's Annual Personal Income (Mean/Median)	$143,102/$90,000	
Annual Total Family Income (Mean/Median)	$271,401.00/$175,000.00	
Hours worked per week (Mean/Median)	54.0/54.0	
Self-employed (% who owned firm)	27.5	
Occupation	Respondent	Spouse
Business Executive	54.8	45.7
Lawyer	11.2	17.2
Physician	0.0	6.2
Government Official	9.0	0.0
College Administrator/Professor	6.2	4.2
Other	18.8	26.0

NOTE: Other includes editor, publisher, author/correspondent, physician, CPA, architect, psychologist, performer/artist

Over 56 percent of the respondents believed that they had a great deal of control over their personal and professional life. An additional 31 and 34 percent in each category (personal and professional, respectively) believed they had a moderate amount of control. In addition, the majority of respondents (77 percent) reported being at least mostly satisfied with their lives.

Respondents furthermore reported that their personal and professional lives had a strongly positive effect on both physical health and mental well-being. In both personal and professional categories, however, the positive effect on mental well-being was stronger than the positive effect on physical health (data available from author upon request).

In general, respondents believed that they were in good health and reported maintaining positive health practices. The mean CDC HRA wellness score, based on a 100-point scale, was 86, with a median score of 87.

This score requires a reference point to indicate where this group falls on the 100-point continuum in comparison with other groups. Although no entirely appropriate comparison group who had completed the CDC HRA could be found for these senior-level executive women, their responses were compared with those from a matched group of working women in the Fitness Research Center data base at the University of Michigan.** Each of the participants in the study group (N = 533)*** was matched on age and education with 20 working women from the Fitness Research Center data base for a total of 10,660. Because neither of the two groups is necessarily representative of all working women nor all executive women, the findings should be interpreted with caution.

**The Fitness Research Center at the University of Michigan maintains a current data base of over 100,000 health risk appraisals collected from the University of Michigan Business School and from diverse data bases provided by investigators from across the United States.

***Twelve cases of the original 545 were not used either because of insufficient data or because respondents were over 70 years of age. Thus, the 533 used represented complete cases.

Table 2 summarizes the CDC HRA health findings from the study reported here and compares them with the CDC HRA health findings from the matched reference group.

The average wellness scores and the risk assessment scores between the two groups were remarkably similar. Yet, further examination reveals several important differences. Fewer of the study group were married than were the matched group with the major difference occurring among those who were divorced. Fewer of the study group smoked than did the matched group, yet far more of the study group reported drinking than did the matched group. Although the number who reported heavy drinking (≥25 drinks of alcohol per week) was small, the study group had over three times as many heavy drinkers as the matched group.

Blood pressure and total blood cholesterol levels were reported as slightly lower among the study group than the matched group.† However, this should be interpreted carefully as the study group of executives was far less knowledgeable about their blood pressure and blood cholesterol values than the matched group. The majority of the executives in the study group did not know either value.

Differences existed between the two groups concerning regular exercise as well as miles driven and seat belt use. The study group exercised more regularly (49 percent) than did the matched group (44 percent). The executives drove, on average, considerably more miles per year than did the matched group and were far more likely to use seat belts (80 percent) than did the matched group (36 percent).

Discussion

This study provides some preliminary data that suggest that the women in executive positions do not necessarily compromise their health. Indeed, this particular group of executive women perceived themselves to be quite healthy, which was supported by their overall wellness and risk assessment scores. In comparisons with a group of age/gender/education-matched working women, the overall wellness and risk assessment scores were remarkably similar. The study group reported greater life satisfaction, stronger social support, and excellent health status. The overwhelming majority of the study group were satisfied with their personal and professional lives and believed that they were in control of both. This perception, coupled with the relatively high wellness scores, suggests that this group of executives may be in better health than had been anticipated as women rose to executive positions within organizations.

The greater numbers of those who drank and who drank heavily, as well as the greater number of divorcees among the study group, requires further examination. Perhaps among a sub-set of these women, there are those for whom the executive lifestyle had a negative effect.

That the executives drink more is not entirely unexpected. Although fewer business lunches and dinners today are conducted with alcohol as an important social ingredient, alcohol is still consumed at such meetings. It may be that alcohol consumption is perceived as a necessary social part of doing business. Or, it may be that these executives really do consume alcohol more often than do other types of working women, possibly as a way of reducing stress. Yet, other behaviors that have been linked to stress reduction,

such as smoking and overeating, appear to be less common with this group of executives compared to the matched group. In fact, more positive stress-reducing activities, such as regular exercise, appear to be practiced by almost half of the executive group.

It is not surprising that at the time of the study (1987) many of the participants and matched group were unaware of their blood cholesterol levels. The National Cholesterol Education Program had just been initiated and related public education was in its infancy. What is surprising is the number of executives who did not know their blood pressure values. The National High Blood Pressure Education Program and its public education efforts have been strong in the United States for the past 17 years. Knowledge about one's "number" and awareness about the disease has been increasing since the inception of this national educational effort. Indeed, knowledge about blood pressure and action to control it has been highly correlated with education and income, especially among females. The reason for this lack of knowledge about blood cholesterol and blood pressure levels is puzzling and is worthy of further investigation.

The greater effort expended on exercise is certainly within keeping among men with higher education. Now Matthews, *et al*, have reported similar findings among women with college and advanced degrees, e.g., the higher the education, the greater the energy expenditure.[38]

While this study may begin to dispel some of those notions of compromised health among women executives, it raises far more questions than it answers. Clearly the study has limitations. It captures only one moment in time and it does not represent all executive women. However, it provides suggestions that might direct further study. The study and the review of the literature argue vigorously for more investigation in this particular area of executive working women, and in the larger concern of the interrelationships of home, work, and health for all working women.

Innovations in State and Local Government Awards Program Invites 1991 Applications

The Innovations in State and Local Government Program has issued a call for applications for its 1991 Innovations Awards Program to recognize creative government efforts at the state, county, municipal, special authority, and tribal levels. Ten winners, selected by a national committee of leaders from government, education, business, and the media, will receive grants of up to $100,000 each by the Ford Foundation.

Entries will be evaluated according to: the program's novelty; its significance in addressing important local and national problems; the value it brings to its clients; and the degree to which it can be replicated by other jurisdictions.

For more information and a 1991 application, contact: Doug Carpenter, Operations Manager, Innovations in State and Local Government, A. Alfred Taubman Center, 79 John F. Kennedy Street, Cambridge, MA 02138; (617) 495-0557.

To be considered, all applications must be received no later than 5:00 p.m., Wednesday, January 9, 1991.

Day Care Characteristics Associated with *Haemophilus influenzae* Disease

Jay D. Wenger, MD, Lee H. Harrison, MD, Allen Hightower, MS, Claire V. Broome, MD,
Haemophilus influenzae Study Group*

Abstract: To identify characteristics of day care facilities associated with *H. influenzae* disease, we compared 92 licensed facilities in which a case of *H. influenzae* disease had occurred with randomly selected facilities at which no cases occurred. Matched univariate analysis showed that personnel at facilities where *H. influenzae* disease occurred were more likely than those at control facilities to use towels or handkerchiefs to wipe children's noses, admit children who were not toilet trained or had diarrhea ("liberal fecal policy"), had a narrower age range, were more likely than control facilities to be for-profit and less likely to use volunteers. In a multivariate model that adjusted for age range, profit status and liberal fecal policy, towel or handkerchief use (OR 5.5, 95% CI: 1.1, 30) was the only variable independently associated with case facilities. This is the first association of a specific day care practice with *H. influenzae* disease. (*Am J Public Health* 1990; 80:1455–1458.)

Introduction

Whereas 20 years ago most children were cared for at home, today most women with children less than 6 years of age are working outside the home, and most of their children receive care at day care facilities.[1,2] Numerous studies have suggested that children attending day care centers were more likely than those cared for at home to suffer from a variety of infectious diseases.[3–9] In particular, attendance at day care facilities is a major risk factor for primary invasive *Haemophilus influenzae* disease.[10–12] Since nearly all *H. influenzae* disease is primary (i.e., is not a result of transmission from another known case), we performed a case-control study comparing licensed day care facilities where a case of *H. influenzae* disease occurred with licensed day care facilities which did not have cases of disease in the same period.

Methods

Surveillance for Invasive *H. influenzae* Disease

Laboratory-based active surveillance for invasive *H. influenzae* disease was performed in four states (Tennessee, Missouri, New Jersey, and Washington) and Los Angeles County, California from January 1, 1986 to December 31, 1986. The details of this system have been previously reported.[13] A contact in each acute care hospital in the area was responsible for reporting to the surveillance coordinator all cases of *H. influenzae* disease from that hospital. A child was considered to be a case of *H. influenzae* disease if *H. influenzae* was cultured from a normally sterile site. When the project ended, surveillance coordinators reviewed ICD-9 discharge diagnosis codes in each hospital to evaluate the sensitivity of the surveillance system.

Selection of Case Day Care Facilities

A child was considered a day care facility attendee if he/she was being cared for along with at least one other unrelated child for at least four hours during the week before becoming ill with *H. influenzae*. The surveillance coordinator contacted the parents of all children between the ages of 1 and 60 months by telephone to determine day care facility attendance. A day care facility was entered into the study only if it appeared on the list of licensed day care facilities provided by the state or county health departments, since no listing of unlicensed facilities existed to select controls for cases attending unlicensed facilities. The director of each case day care facility was contacted by telephone and, after explanation of the study, offered the opportunity to participate. If a case day care facility refused to participate, the case was eliminated from the study. If the director of the case day care facility agreed to cooperate, the surveillance coordinator obtained the case center's characteristics via questionnaire at that time.

Selection of Control Day Care Facilities

For each enrolled case day care facility a size-weighted, randomly ordered list of licensed day care facilities in the surveillance area was generated. The first day care facility on the list was chosen as a control day care facility if it:

- matched the case day care facility for type, i.e. day care home (in a residence) or nonresidential day care center;
- was not a case day care facility itself; and
- had not already been selected previously as a control.

The director of each potential control day care facility was contacted by telephone until a day care facility was found that would have cared for children in an age range including the age of the case at the time of case admission and was willing to participate.

Statistical Methods

Univariate and multivariate models were evaluated using matched conditional logistic regression.[14] Analyses performed on subsets of the data (for example, for cases under two years of age or for day care homes vs day care centers) contained only sets where both the case and control met the

criteria. Multivariate modeling was hypothesis-oriented and did not use stepwise variable selection methods.

Results

Surveillance and Identification of Case/Control Pairs

During 1986, 1,230 cases of invasive *H. influenzae* disease in children less than or equal to 60 months of age were reported from the five surveillance areas. ICD-9 discharge diagnosis code reviews were available for all surveillance areas except New Jersey. Of 408 cases reported by discharge diagnosis, 370 (90 percent) were detected by active surveillance. Day care status was determined for 1,081 (88 percent) of the 1,227 cases. A total of 358 cases attended day care facilities. Of these, 198 (57 percent) attended unlicensed day care facilities, and further information was not available for another 26 (7 percent), due to parental unwillingness to identify the facility. Parents or day care facility directors of 14 of the remaining 134 cases refused to participate. An additional four cases were deleted from the analysis because they occurred in facilities already enrolled as cases in the study, and we did not want to represent the same case facility twice in the analysis. These four facilities were not clearly different from other case facilities. Case and control pairs were obtained for 92 of the remaining 116 eligible cases (79 percent). The 24 eligible cases for whom controls were not available did not differ from the 92 included in the study by age, sex, race, or clinical syndrome, nor did their facilities differ by type or size or any of the variables associated significantly with case facilities in the univariate analysis. Sixty-nine case and control pairs were non-residential facilities (day care centers) and 23 pairs were residential facilities (day care homes). There were no significant differences in age, sex, race, or disease syndrome between day care attendees who were enrolled in the study and those who were not enrolled (Table 1).

Risk Factors

Univariate Analysis—Table 2 shows odds ratios of potential risk factors for *H. influenzae* disease in the analysis of all day care facilities regardless of age of case, enrollment, or type of facility. Separate analyses stratifying for age of case (less than or equal to 2 years of age, or older than 2 years of age), enrollment (less than or equal to 20 or greater than 20 children/day care facility) and type of day care facility (day care home vs day care center) did not identify other risk factors except as noted below.

TABLE 1—Characteristics of Day Care-Associated *H. influenzae* Cases

Characteristics	Cases Enrolled in Case-Control Study n = 92 (%)	Cases Not Enrolled* n = 266 (%)
Sex		
Male	49 (53)	130 (49)

Blood only	33 (35)	91 (34)

Note: Percent in parentheses.

*Because of unlicensed or unknown licensure status of facility, or refusal by parents or day care facility.

Age Range—The mean age range of children cared for in case-day care facilities was 67 months, while that in control centers was 83 months ($p = 0.023$). This difference was primarily a function of the difference in the mean age of the oldest child in the day care facility, since the mean age of the youngest child did not differ significantly between case and control day care facilities (due partly to the matching design).

Exclusion Policies—As shown in Table 3, control day care facilities were more likely to exclude children with diarrhea than were case day care facilities (OR 0.35, 95% CI: 0.14, 0.90). The two variables measuring exposure to feces were combined to form a third variable—liberal fecal policy (accepting non-toilet-trained children (Table 1) or not excluding children with diarrhea). The univariate odds ratio for liberal fecal policy was 3.3 (95% CI: 1.3, 8.3).

Business Status—Failure to use volunteers and for-profit status were highly associated variables with 15 percent of for-profit facilities using volunteers, compared with 39 percent of non-profit facilities ($p < 0.001$). Not using volunteers had an odds ratio of 2.6 and for-profit status had an odds ratio of 1.4.

Other Factors—Several other factors evaluated are listed in Table 2. Of note, use of a towel or handkerchief to wipe childrens' noses was associated with case day care facilities with an unadjusted odds ratio of 4.5.

Multivariate Analysis—A multivariate model was used to evaluate the significance of potential risk factors which were hypothesized to be related to disease and which, in the univariate analysis, showed either elevated (or reduced) odds ratios or associations ($p < .05$) with case facilities. Since two pairs of variables were closely related (age range/age of oldest child, and profit status/use of volunteers), only one of each pair was used in the multivariate analysis. The results of a multivariate model constructed with the variables of age range, profit status, liberal fecal policy and towel or handkerchief use are summarized in Table 4. Towel or handkerchief use is the most strongly associated variable (OR 5.5, 95% CI = 1.01, 30).

Discussion

During the course of this study, we found, as have others,[15] that many day care facility characteristics are closely associated. The matching technique and the association of many day care facility characteristics with the matching variables may have decreased our ability to identify risk factors in this study.

Use of towels or handkerchiefs to wipe childrens' noses was the most important risk factor for occurrence of *H. influenzae* disease in our multivariate model. This practice may facilitate transfer of the pathogen from child to child, since spread of *H. influenzae* organisms occurs through exchange of oropharyngeal secretions. The towel-handkerchief variable may represent a direct means of person-to-person spread of *H. influenzae*. *H. influenzae* organisms adhere to human nasopharyngeal mucous.[16] Murphy, *et al*, recently found that nasal secretions of *H. influenzae* carriers had much higher concentrations of *H. influenzae* than cough or oropharyngeal secretions, and that *H. influenzae* could

survive for up to 48 hours on fomites such as water-absorbent towels.[17] Our study provides evidence that the route of transmission hypothesized by the laboratory studies of Murphy, *et al*, is important in day care facilities.

Several organizational characteristics were associated with case day care facilities in the univariate analysis. Case day care facilities were more likely to have a narrower age range and younger age of eldest child than control day care facilities. The age of youngest child in the day care facility did not differ. When day care centers were analyzed separately, these risk factors were still present. The same trends were present for day care homes, but were less stable. Although the association of narrower age range with risk of disease may be related to having more children of a younger age (and therefore at higher risk of *H. influenzae* disease) in a case day care facility, we could not evaluate this possibility since information on age of every child in each day care facility was not collected. However, neither number of classrooms nor number of children <23 months of age in each classroom differed between case and control day care facilities.

Slightly more control day care facilities than case day care facilities advised or required vaccination for *H. influenzae*, but the difference was minimal (42–44 percent vs 34–40 percent, depending on age of the child). It is unlikely that this difference accounted for lack of disease in control day care facilities because of the small size of the difference, and because more than two-thirds of all cases occurred in children too young to receive the vaccine (less than 18 months of age). The trend toward a more active vaccination policy, however, may represent better awareness of the disease and means of prevention.

Liberal fecal policy (evaluated because colonization with some enteric bacteria with cross-reacting antigens may be important in *H. influenzae* disease),[18] profit status, and age range were less strongly associated with case day care facilities. These variables were all related and may be surrogates for other more specific risk factors. For instance, profit status was also associated with hepatitis A incidence in the study of day care facilities in Arizona.[15] Although several other day care facility characteristics are likely to be associated with whether the facility is run as a for-profit or non-profit organization, it was not clear (from either this or the previous analysis of hepatitis A in day care facilities) how this could relate causally to incidence of *H. influenzae* disease.

Although a role for use of towels or handkerchiefs to wipe noses in transmission of infectious diseases has been suggested previously, this is the first study to identify it as a risk factor in the day care setting. Additional measures must be taken to eliminate this practice. Several other variables less strongly associated with risk of disease included liberal fecal policy, profit status, use of volunteers, and age range. They may be surrogates for more specific risk factors which remain to be identified.

NIH Consensus Panel Issues Report on IVIG

Earlier this year, the National Institute of Allergy and Infectious Diseases and the Office of Medical Applications of Research of the National Institutes of Health convened a Consensus Development Conference on *Intravenous Immunoglobin: Prevention and Treatment of Disease*.

The consensus panel has now issued its report containing conclusions and recommendations from this conference.

Single copies of the report may be obtained from: William H. Hall, Director of Communications, Office of Medical Applications of Research, NIH, Bldg. 1, Rm 259, Bethesda, MD 20892; (301) 496-1142.

OMAR will also provide multiple copies of a two-page summary statement of the conference findings to organizations that wish to distribute copies to its members.

Injury and Disability in Matched Men's and Women's Intercollegiate Sports

Richard R. Lanese, PhD, Richard H. Strauss, MD, Daniel J. Leizman, MD, and Ann Marie Rotondi, MA

Abstract: Eight matched men's and women's intercollegiate varsity teams were studied prospectively for one academic year to determine the incidence of athletic injury and resulting disability. Sports in which both men and women participated in a comparable manner were chosen: basketball, fencing, gymnastics, swimming, tennis, indoor track, outdoor track, and volleyball. Men (232) and women (150) were injured at comparable rates, 42 percent versus 39 percent. When adjusted for exposure time, seven of the eight sports continued to show similar injury rates. Women gymnasts, however, experienced .82 injuries per 100 person-hours of exposure as compared to .21 injuries for the men ($p = .0001$). Disability was greater in women gymnasts, 7.44 days per 100 person-hours versus 1.15 days for men ($p = .0004$). Percent of season lost to injury was also greater for women gymnasts. Types and sites of injury were similar for men and women, with sprains and strains accounting for over half of all injuries. We found no evidence for gender differences in matched sports except for gymnastics, in which technically diverse events may have accounted for the differences observed. (*Am J Public Health* 1990; 80:1459–1462).

Introduction

Women's participation in intercollegiate athletics has increased dramatically in recent years. Several studies comparing injury rates in men and women participating in similar sports have reported conflicting results.[1–3] Some studies have noted higher injury rates in female gymnasts and basketball players.[4–7] However, few studies have been conducted on mature men and women.[8–10]

In view of the conflicting results of previous studies and the paucity of information on mature athletes, the present study was undertaken to provide injury data on men and women engaged in similar sports while controlling for the length of time each athlete was exposed to injury. Earlier studies have rarely controlled for exposure time. If gender differences are observed, a larger study may be designed to investigate possible risk factors such as technical differences within a sport or biological differences associated with injury.

Methods

The study was conducted as a prospective cohort study for the period of one academic year at a large university. Eight matched men's and women's varsity sports were studied. These were sports in which both men and women participated in a comparable manner and included basketball, fencing, gymnastics, swimming, tennis, indoor track, outdoor track, and volleyball.

One of the authors (A.M.R.) visited each team weekly to record the appropriate injury information for the week. Injury data came from the medical records kept by the team physicians and by certified and student athletic trainers.

An athletic trainer or student trainer was present at each team practice and competition and was responsible for collecting the injury and disability data. Injuries not attributable to the team sport, as well as all illnesses, were excluded from the study.

We defined an injury as a traumatic medical problem due to sports participation and resulting in loss of time from practice or competition. When an injury occurred during practice or competition and the athlete was unable to complete the day's activity, one-half day of disability was assigned. One whole day of disability was assigned for each full day of practice or competition lost. On weekends, teams usually had only one day off. For example, if an athlete was injured on Saturday, had no scheduled practice on Sunday, and returned to practice on Monday, half of Sunday was assigned as injury time off. Disability days were calculated for each athlete.

We studied each team from the first official day of practice until the last day of regular competition or practice. Hours of practice and competition were estimated by either direct observation or interviews with coaches and athletes, or a combination of both methods. This provided indices independent of differences in exposure time. Exposure time was calculated for each athlete and for each sport by subtracting disability days as well as other absences from the total time available for practice and competition.

To compare injuries between men and women, we utilized the following indices: 1) injuries per 100 persons; 2) injuries per 100 person-hours of exposure; 3) disability days per 100 person-hours of exposure; 4) percent of season lost to injury; and 5) percent of persons injured. These indices were computed for each athlete and each team. Because injuries were not normally distributed and, more than likely, not independent, the nonparametric Wilcoxon Rank Sum statistic,[11] corrected for ties, was employed to test gender differences within each sport and for all sports after assigning an injury rate to each athlete. This procedure was used for two indices: injuries per 100 person-hours of exposure, and percent of season lost to injury. The Mantel-Haenszel statistic[12] provided a test of difference in the proportion of men and women injured over all sports together. The relative risk of injury and its 95% confidence interval was estimated for males using the direct precision-based method.[13]

If the true proportions of male and female athletes who are injured are in the range of 40 percent to 60 percent, the present study sample has approximately an 80 percent chance of detecting a 15 percent difference when alpha is at .05.

Types of injury and anatomical sites were also determined. No practicable statistical methods of analyses were available to evaluate gender differences for these parameters.

Results

The study cohort was composed of 232 men and 150 women. Table 1 shows the frequency and percent injured for

All Sports	M	232	98 (42)*	154	66
	F	150	58 (39)	91	61

*Relative risk = 1.25 (CI 0.88, 1.43).

each of the eight matched sports. While the percentage of athletes injured varied considerably between sports, within sports there appear to be only small and inconsistent gender differences. For all sports combined, where 42 percent of the men and 39 percent of the women were injured, the Mantel-Haenszel χ^2 was 0.53 ($p \approx .50$). The relative risk, adjusted for between sport differences, was 1.25 with a 95% confidence interval of 0.88 to 1.43.

The rate of injury expressed as injuries per 100 persons was similar for all sports combined, 66 injuries per 100 persons for men, and 61 per 100 persons for women. Both men and women participating in gymnastics appear to have higher rates of injury than athletes in the other sports. All but one of the 35 gymnasts reported at least one disabling injury during the season. Women gymnasts were injured at a somewhat higher rate than men—273 versus 217 per 100 persons, respectively. When the incidence of injuries is expressed in terms of exposure time, women gymnasts sustained 0.82 injuries per 100 person-hours of exposure, while men incurred only 0.21 injuries (Table 2). This difference was significant by the Wilcoxon Rank Sum Test ($p = .0001$). There were no gender differences observed for the seven other sports nor for all sports combined.

Table 2 also summarizes disability days for men and women by sport. Women gymnasts had the highest rate of disability, 7.44 days per 100 person-hours of exposure, while men gymnasts had only 1.15 disability days, a sixfold difference ($p = .0004$). We were unable to detect gender differences in any of the remaining seven sports and, more importantly, when all eight sports were combined. For all sports, both men and women missed 1.4 days for every 100 hours of exposure, a period approximated by five to six weeks of practice and competition.

The types and sites of injury occurring during the period of study appear to be similar for both men and women. Strains and sprains were clearly the most common types of injury (Figure 1), accounting for over half of all injuries for both men and women.

The most frequent site of injury was foot and ankle (Figure 2). There appears to be little difference between sexes with respect to site. However, on closer inspection, injuries to the upper extremity (shoulder, upper arm, hand, wrist, elbow, and forearm) occurred more frequently in men (27 percent of injuries) than in women (13 percent of injuries).

Discussion

We relied on the medical records as kept by the team physicians and athletic trainers. The data were reviewed and accumulated once each week by one of the authors. We assumed that the reporting of injuries would be equally reliable across all sports and gender.

The present study involved 382 men and women over a period of one year at a single university. Thus, the question of repeatability of the findings from year to year, as well as the generalizability of the findings from one setting to another, may be questioned. While the total number of athletes studied was fairly large, the number of men and

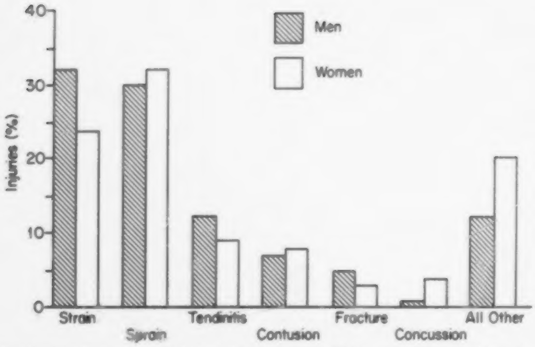

FIGURE 1—Percent of Injuries by Type among Male and Female Athletes in Eight Matched Intercollegiate Sports during One Year at a Large University

women in each paired sport was relatively small, resulting in low statistical power for detecting sport-specific gender differences. While gender differences in gymnastics were sufficiently large to overcome this problem, there may be differences in other sports that we were unable to detect.

Our estimates of exposure time for each athlete are crude, but should be useful when comparing gender differences for a single sport. For example, in basketball, men and women play the game in a similar manner and probably have comparable periods of activity and inactivity. To the extent that this is true, any gender difference in observed rate will be free of bias from exposure difference in a given sport.

We expected modest differences in exposure times between women and men in the same sport. However, we did not anticipate the size of the differences observed. For the 16 teams, exposure times ranged from 92 hours for women's outdoor track to 1,020 hours for men's gymnastics. It is clear from Table 2 that within-sport and between-sport comparisons of injury must take these exposure differences into account. Gymnastics reflects the greatest exposure disparity between women and men, 365 hours and 1,020 hours, respectively. Yet, women report a higher incidence of injuries per 100 persons.

We found little difference between men and women in terms of injury or disability in the eight sports except for gymnastics. Other investigators[2,10,14] as well, have reported differences in injury rates and types of injury in male and female gymnasts, with females showing somewhat higher rates. The differences that we observed are largely a result of expressing injuries in terms of exposure time. Only small differences between the sexes were observed when injuries were expressed per 100 persons or as percent of persons injured (Table 1).

When we expressed disability as the percent of season lost for each athlete, the median for women gymnasts, 8.21 percent, was significantly higher than the median for men, 3.15 percent ($p < .01$). No other team lost as high a percentage of their season due to disability. Ten of the 14 teams had medians at zero percent.

It is generally accepted that men gymnasts use predominantly upper body musculature and women use predominantly lower body musculature. This is consistent with the upper extremity injury difference noted earlier. The injury and disability differences that have been reported in this paper and elsewhere may be more a consequence of the different types of events and apparatus than of gender. Women gymnasts participate in four events and men in six. Only two of the events utilize the same apparatus: floor exercise and vault.

It is interesting to note that, while women and men gymnasts comprised only 9 percent of the athletes followed during the year of study, they accounted for almost 34 percent of all injuries. The apparent excess of injuries in gymnasts may be a result of the special requirements of the sport. Injuries that might be regarded as inconsequential and not reported by athletes in other sports such as football may impair the performance of the gymnast.

The main finding of this paper suggests that, when men and women compete in sports that are technically similar, the

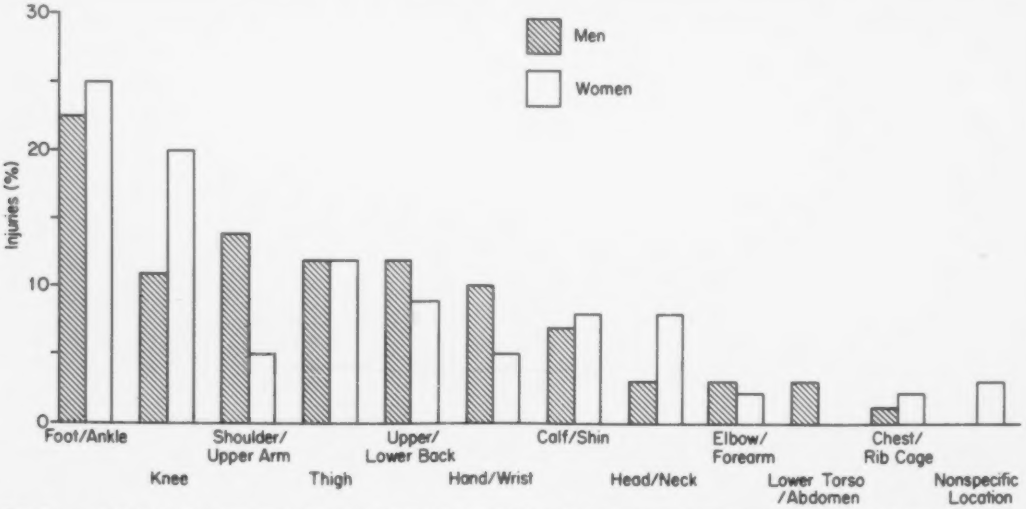

FIGURE 2—Percent of Injuries by Site among Male and Female Athletes in Eight Matched Intercollegiate Sports during One Year at a Large University

rates of injury are approximately equal. When they compete in sports that are technically different, there is little reason to expect injury rates to be the same. This may account for our single positive finding—that men and women gymnasts differed in injury rates.

National Conference on Cancer Nursing: Call For Abstracts

Nursing professionals are invited to submit abstracts for poster presentations for the American Cancer Society's Sixth National Conference on Cancer Nursing. The conference, "From Primary to Tertiary Care: Cancer Across the Life Span," will be held July 25–27 in Seattle, Washington.

Within the theme, abstract topics may be related to clinical practice, education, research, and nursing administration. The deadline for abstract submission is February 1. For additional information, contact: Terri Ades, RN, Coordinator for Nursing Programs, ACS National Office, 1599 Clifton Rd, NE, Atlanta, GA 30329; (404) 329-7655.

This conference is the sixth in a series of national nursing conferences which are held every four years, and whose purpose is to improve the quality of cancer care provided to individuals and their families. The conference program is directed at nurse generalists, primary care nurses, oncology nurses, and other members of the health profession whose practice is devoted to providing care to individuals and their families throughout the life span. The conference is sponsored by the American Cancer Society, in cooperation with the American Nurses' Association Council on Primary Health Care Nurse Practitioners, Association of Pediatric Oncology Nurses, and the Oncology Nursing Society.

Coding External Causes of Injury (E-Codes) in Maryland Hospital Discharges 1979–88: A Statewide Study to Explore the Uncoded Population

BARUCH MARGANITT, MD, MPH, ELLEN J. MACKENZIE, PHD, GORDON S. SMITH, MBCHB, MPH,
AND ANNE M. DAMIANO, SCM

Abstract: We examined the trends in hospital discharge E-coding in Maryland over a 10-year period. The overall proportion of E-coded discharges has increased from 40 percent in 1979 to 55 percent in 1988. E-coding was lower in the severely injured, the elderly, and patients with long hospital stays. Our findings demonstrate that E-code reporting varies because of the limited number of data fields available for coding of discharge diagnoses. Universal, systematic reporting of E-codes in hospital discharge data is essential if these data are to provide critically needed information about nonfatal injuries. Hospital discharge data formats should contain separate fields for E-codes and the use of these codes, we believe, should be mandated. (*Am J Public Health* 1990; 80:1463–1466).

Introduction

Efforts to examine trends in the incidence of injury, patterns of acute care, and patient outcomes have generally required substantial investments in case ascertainment and data collection. The increasing availability of computerized statewide hospital discharge data offer new opportunities for timely and efficient data collection and policy analysis of issues related to the prevention of injuries and trauma care delivery.[1–8] The recent development of a computerized conversion table that translates ICD-9CM coded discharge diagnoses into Abbreviated Injury Scale (AIS) scores has led to new applications of these databases, providing population-based data specific to the severity of injuries.[8–11] Currently, 28 states require that uniform hospital discharge data be collected on all acute care hospitalizations.[8]

The lack of consistent coding of the external cause of injury limits the usefulness of these databases.[12,13] Although a classification of external causes exists within the structure of the International Classification of Diseases (ICD E-codes-),[17] hospitals vary in their use of these codes. Accurate data on the causes of nonfatal injuries and a means to measure their trends are not available in the United States. Underreporting of E-codes in hospital discharge abstracts has been recognized as a major limitation in their use for these purposes.[12–15]

To better understand factors responsible for incomplete E-coding, we analyzed 10 years of Maryland hospital discharge data. The specific objectives of the study were: to examine time trends in the level of E-coding in the statewide population-based hospital discharge data; and to determine demographic and clinical characteristics of the uncoded population (the missing E-code population), in order to identify strategies for improving reporting of E-codes.

Methods

Uniform hospital discharge abstract data for the state of Maryland during the 10 years from 1979 to 1988 were used to examine trends in E-coding over time. All 52 non-federal acute care hospitals in Maryland are mandated by law to submit uniform data to the State's Health Services Cost Review Commission (HSCRC). External causes of injury are reported as ICD-9CM E-Codes and can be included in the database as one or more of five possible discharge diagnoses.

The Study Population consisted of the 349,487 hospital discharges in the state of Maryland with a principal diagnosis of traumatic injury. Traumatic injuries were defined as those injuries coded with ICM-9CM diagnoses codes 800–959 excluding: late effects (905–909), foreign bodies (930–939), and early complications (958). Poisonings (960–979), toxic effects (980–989), other and unspecified effects of external causes (990–995), and complications of medical and surgical care (996–999) were also excluded. E-coding status of each discharge abstract was defined as one of the following three categories based on existence of an E-code and availability of ICD-9CM code recording space: 1) E-coded discharge, 2) Uncoded discharge with no coding space available (no E-code, not codable), 3) Uncoded discharge with coding space available (no E-code, codable). Using the 1988 data, coding status was examined by age of the patient, injury severity, body region of the injury assigned as the principal diagnosis (head-neck/extremities), length of hospital stay, and level of hospital care, i.e.: 1) Specialty Referral Trauma Centers (SRTC) (One adult and one pediatric); 2) Regional Trauma Center (RTC) (nine centers); 3) Community Hospital (Com Hosp) (41 hospitals). Injury Severity was assessed by the Injury Severity Score (ISS)[16] and was assigned to each discharge using the ICDMAP software[9,10] that maps ICD-9CM coded diagnoses into Abbreviated Injury Scale (AIS) scores and ISS. E-code status was examined for the 10 years 1979–1988.

Results

The proportion of E-coded trauma discharges increased over the study period by 38 percent, from 40 percent in 1979 to 55 percent in 1988 (Figure 1). Over the same period, however, the proportion of uncoded discharges that had vacant space available for additional codes (no E-code, codable) decreased from 98 percent in 1979 to 53 percent in 1988.

Increasing age was associated with a decrease in the percent of E-coded discharges as well as an increase in the proportion of not codable discharges (Figure 2). In 1988, the year with the highest coding rate, 73 percent of the 0–5 age

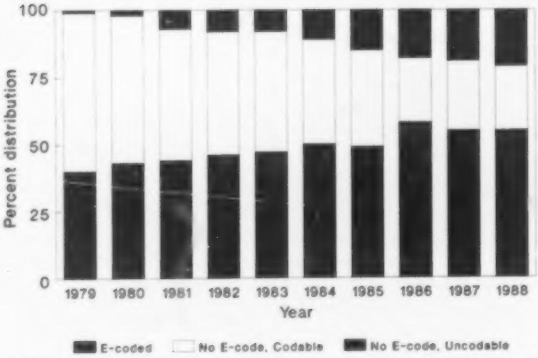

FIGURE 1—E-Coding Status by Year, Maryland Trauma Discharges, 1979–88

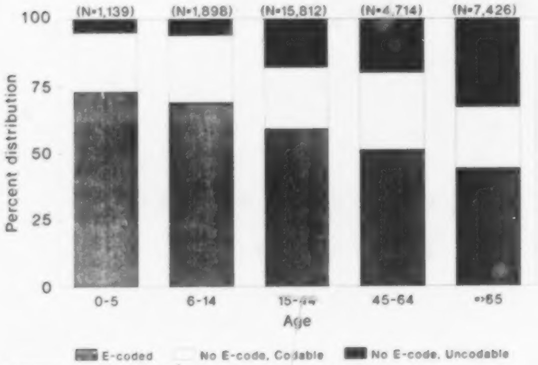

FIGURE 2—E-Coding Status by Age, Maryland Trauma Discharges, 1988

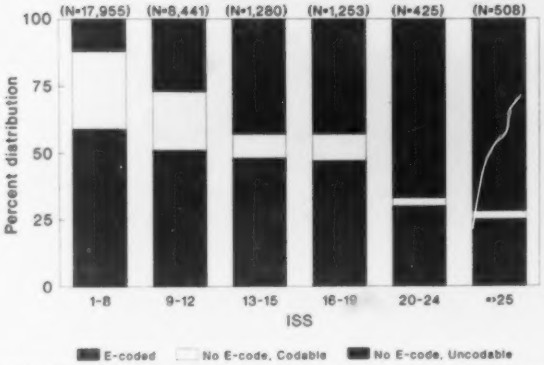

FIGURE 3—E-Coding Status by Injury Severity Score, Maryland Trauma Discharges, 1988

group discharges were E-coded as compared to 44 percent in the ≥65 age group. However, in age group 0–5, 18 percent of the uncoded discharges were not codable, as compared to 59 percent in age group ≥65. This differs from earlier study years; in 1979, for example, the proportion of E-coded discharges ranged from 44 percent in 0–5 age group to 40 percent in ≥65, while the percent of uncoded discharges that were not codable ranged from 0–1 percent.

As the Injury Severity Score (ISS) increased the proportion of E-coded discharges decreased and the proportion of uncoded discharges that were not codable increased (Figure 3). In 1988, the proportion of E-coded discharges ranged from 59 percent of ISS group 1–8 to 25 percent of ISS ≥25. However, in ISS group 1–8, 29 percent of the uncoded discharges were not codable, as compared to 92 percent of the uncoded discharges of ISS group ≥25. In the early years of the study period, E-coding status did not vary with ISS; for example, in 1979, the proportion of E-coded discharges ranged from 42 percent of ISS 1–8 to 39 percent of ISS ≥25; out of the uncoded discharges the percent of not codable discharges, however, was very low ranging from 0–2 percent.

Table 1 compares the 1988 E-coding status within ISS subgroups between the two most prevalent body-region categories: head/neck and extremities. In both groups the proportion of E-coded discharges decreased with increasing ISS. However, the proportion of coded discharges in the extremities group was lower than the head-neck group in all ISS categories, with more notable differences in the most severe groups (ISS 16 and higher). There were also marked differences between the head/neck and extremities groups in the proportion of uncoded discharges that were not codable. For example, in the ISS 16–19 Head/Neck group 47 percent of the discharges were uncoded, and 72 percent of them were not codable. This is compared to discharges with a principal injury to the extremities of which 76 percent were uncoded, and of them 95 percent were not codable.

In 1988, 64 percent of the 1 day LOS group were E-coded, as compared to 25 percent of the 29–56 days, and 12 percent of LOS ≥57 days (Figure 4). Of the uncoded discharges the proportion that were not codable increased from 17 percent of the uncoded discharges in the 0–1 day LOS group to 96 percent of the uncoded discharges in the ≥57 days LOS group.

E-coding increased over the study period in all levels of care, however trauma centers coded a higher proportion of discharges. For example, in 1988 over 60 percent of trauma center discharges were E-coded as compared to 47 percent of the discharges from community hospitals (Figure 5). In community hospitals, 70 percent of the uncoded discharges were codable, as compared to 28 percent and 7 percent of the uncoded discharges in Regional Trauma Centers and Specialty Referral Trauma Centers, respectively.

Discussion

This study demonstrates that the current structure of many statewide hospital discharge data systems restricts the use of E-codes for specific subgroups of patients. In Maryland, reporting of E-codes is not required and is done inconsistently across hospitals and patients. In many hospital discharge data systems, including HCFA's UB-82, E-codes can only be included in the discharge abstract as one of five discharge diagnoses.[13] Since ICD E-codes are not used as a basis for reimbursement, they receive low priority in the selection process of the five ICD-9CM codes reported.[14] Thus E-coding rates are lowest among selected groups of patients that are typically characterized by large number of discharge diagnoses, i.e. severely injured patients having multiple injury-related diagnoses, the elderly patients who are likely to have chronic diseases existing prior to the trauma and are more prone to complications leading to additional discharge diagnoses, and the patients with long hospital stays either due to severe injuries or complications. Injuries, preexisting chronic conditions and complications all take precedence

TABLE 1—E-Coding Status by Body-Region of Principal Diagnosis and by ISS, Maryland Trauma Discharges, 1988

	%E-Coded		% No E-Code Codable		% No E-Code Uncodable		Total

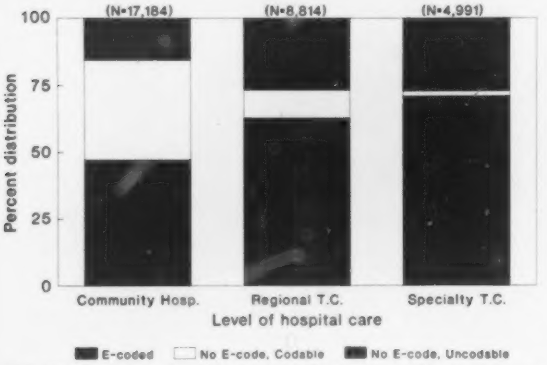

FIGURE 5—E-Coding Status by Level of Hospital Care, Maryland Trauma Discharges, 1988

over cause in coding since they may influence the rate at which hospitals are reimbursed.[14]

In Maryland, the proportion of E-coded trauma discharges has increased from 40 percent in 1979 to 55 percent in 1988. This is likely due to increasing awareness and interest in injury control and Emergency Medical Services (EMS) in the state. Of the uncoded discharges, however, the proportion that were codable has decreased from 98 percent in 1979 to 53 percent in 1988. This trend was most marked in the selected groups of patients described above. This finding suggests that while there is an increasing awareness of the importance of E-coding in the state, there is less potential for including an E-code in the hospital discharge data. This is likely due to the increased attention paid to characterizing the full extent and nature of the injury, complications, and comorbidities and utilization of all five ICD-9CM coding spaces.

Simply increasing the number of fields for recording diagnoses, however, is not an adequate solution. In California, for instance, where a maximum of 25 hospital discharge diagnoses can be recorded,[18] only 40 percent of the trauma discharges in 1983 have been E-coded (MacKenzie EJ, unpublished data). Rather, it will be necessary to mandate E-coding and provide data fields separate from those available for recording diagnoses, preexisting medical conditions, and complications. Mandatory E-coding legislation or regulation, as initiated in New York, California, Wisconsin, and Washington State,[13] and more recently in Rhode-Island and Vermont, provide the means to ensure better compliance with E-coding practice. As has been demonstrated in this study, however, it is essential that separate fields for recording of E-codes be created otherwise it may not be recorded on computerized data bases for those injury cases with multiple diagnoses. There is a need for two E-coding fields in order to adequately characterize the external cause and intent of the injury.[19] Monitoring trends in E-coding rates in these states will be important to assess the extent of compliance and accuracy. Mandating that trauma discharges be E-coded will only be effective if hospital coders are properly trained.[13] Computer software recently developed by the Centers for Disease Control should assist in simplifying E-coding and increase in reliability.[20] In addition, training manuals and courses for E-coding are now available.[19]

Until such time as E-codes are uniformly recorded for all trauma discharges, caution must be exercised when extrapolating results by cause of injury based on only those discharges that are E-coded. This study shows systematic underreporting of external causes of injury in specific trauma patients groups such as the elderly, the severely injured, etc. At the very least, extrapolations should only be made within strata of the population defined by age of the patient and the nature and severity of the injuries sustained. It is also important to recognize that patterns of E-coding may vary over time, by geographic region and by hospital type and coding practices. Gathering cause of injury data from different databases requires attention to the scope and direction of E-code reporting bias that each system may introduce.

Hospital discharge data represent an important and usually the only source of population-based data on serious, nonfatal injuries. Systematic, uniform, and reliable reporting of E-codes in these databases would provide essential information for monitoring trends and patterns of injury, defining subgroups of the population at high risk of injury, and in developing and evaluating injury prevention programs.

New AHCPR Publications Catalog Available

The Agency for Health Care Policy and Research has published an updated catalog of publications available from its Center for Research Dissemination and Liaison.

The 11-page catalog provides brief descriptions of program publications (bibliographies, research information, and other documents) and subject area reports in the following categories: financing, costs, expenditures, insurance; HIV/AIDS; hospitals; long-term care; quality assurance and patient outcomes; research methods and models; service delivery, access, and utilization; and technology assessment.

Single copies of *Publications in Print, 1990* are available from: AHCPR, Publications and Information Branch, 18–12 Parklawn Bldg., Rockville, MD 20857; (301) 443-4100.

Benzodiazepine Tranquilizers and the Risk of Accidental Injury

Gerry Oster, PhD, Daniel M. Huse, MA, Shelley F. Adams, MPA,
Joseph Imbimbo, BA, and Mason W. Russell, MAPE

Abstract: To determine whether benzodiazepine tranquilizers increase the risk of accidental injury requiring medical attention, we used pharmacy claims submitted to a large third-party payer to identify 4,554 persons who had been prescribed these agents and a matched control group of 13,662 persons who had been prescribed drugs other than benzodiazepines. We then used diagnoses recorded on claims submitted by medical care providers to identify all accident-related care received by these persons during three months before their first-observed prescription for a benzodiazepine or nonbenzodiazepine agent, respectively, and six months subsequently. We found accident-related care was more likely among persons who had been prescribed benzodiazepines; among these persons, the probability of an accident-related medical encounter was higher during months in which a prescription for a benzodiazepine had recently been filled compared to other months; and persons who had filled three or more prescriptions for these agents in the six months following initiation of therapy had a significantly higher risk of an accident-related medical event than those who had filled only one such prescription. Approximately two-fold risks of accident-related care were found, after controlling for age, sex, and prior utilization. (*Am J Public Health* 1990; 80:1467–1470.)

Introduction

Benzodiazepine tranquilizers were introduced in the United States in 1962 and rapidly supplanted barbiturates as anxiolytic agents of first choice. While they are among the most widely prescribed classes of drugs, there is mounting evidence that their use impairs cognitive performance and psychomotor skills. Persons given benzodiazepines have been found to perform poorly in driving simulator tests relative to those receiving placebo.[1,2] In addition, several forensic studies[3–6] have found a greater than expected number of benzodiazepine users among persons fatally injured in motor vehicle accidents.

Three epidemiologic investigations of impairment related to the use of minor tranquilizers have been reported to date. A study conducted in England over a two-year period found that patients receiving benzodiazepines and other minor tranquilizers were nearly five times more likely to experience a serious motor vehicle accident than those who had not used these drugs.[7] Another study examined persons hospitalized for injuries resulting from a motor vehicle accident and found that persons identified as drivers who were at fault in their accidents were somewhat more likely to have filled a prescription for hypnotics or tranquilizers during the three-month period prior to the accident than those identified as passengers.[8]

The third epidemiologic investigation, a retrospective cohort study using claims data from a large health insurer,[9] compared accident-related medical care among persons who were prescribed benzodiazepines with that of a matched control group who had not been prescribed these agents. Persons prescribed benzodiazepines were more likely to have accident-related care, but also were reported to experience a greater number of nonaccident-related medical encounters, suggesting differences in care-seeking behavior rather than risk of accidental injury. Without data on medical utilization prior to therapy, the effect of differences in care-seeking behavior could not be determined.

To circumvent this difficulty, in the present study we employ a pretest-posttest design[10] to examine three key questions: 1) Are persons who are prescribed benzodiazepine tranquilizers more likely to require accident-related medical care? 2) Is there evidence of a temporal relation between prescriptions for these agents and the likelihood of an accident-related medical encounter? 3) Is there evidence of a relation between the number of such prescriptions and the risk of these encounters?

Methods

Data Source

Data for this study were obtained from the health care claims processing system of Master Health Plus™, a health insurance plan operated by Blue Cross and Blue Shield of Massachusetts with a membership in excess of one million persons. Plan members receive first-dollar coverage for physician services, inpatient and outpatient care, and prescription drugs, with a $5 copayment for provider services, a $4 copayment for prescription drugs ($3 for generics), and a $500 annual limit on reimbursement for mental health services. All claims for care are provider-submitted, and nondrug claims contain detailed diagnostic information in the form of physician-recorded ICD-9-CM codes. A complete record of medical utilization may be compiled for each plan member during his or her period of enrollment.

To be eligible for inclusion in the present study, members had to be enrolled continuously in the plan during the period April 1986–September 1987. Persons over 65 years of age or otherwise eligible for Medicare benefits were excluded from the study because Medicare claims were not available.

For our sample of persons who were prescribed benzodiazepines (benzodiazepine "users"), we selected all eligible plan members who had at least one pharmacy claim for a benzodiazepine tranquilizer (alprazolam, chlordiazepoxide, clorazepate, diazepam, lorazepam, or oxazepam, either singly or in combination with any other agent) during July 1986–March 1987, and had no claims for any of these agents between April 1986–June 1986. We considered the date of the first-observed pharmacy claim for a benzodiazepine agent to be the date of initiation of benzodiazepine therapy. A total of 4,554 benzodiazepine users were identified and included in the study.

This paper, submitted to the Journal July 11, 1989, was revised and accepted for publication April 17, 1990.

Three persons who were not prescribed benzodiazepines (benzodiazepine "nonusers") were matched randomly to each user. Nonusers were selected from among those eligible patients who had no pharmacy claims for a benzodiazepine tranquilizer between April 1986–March 1987, were not related by blood or marriage to any patient who had a claim for such an agent during April 1986–March 1987, and had at least one claim for a nonbenzodiazepine agent during July 1986–March 1987. We considered the date of the first-observed nonbenzodiazepine drug claim to be the date of therapy initiation for each nonuser, and we matched nonusers to users on the basis of age, sex, and the calendar month during which therapy was initiated.

For each person in the sample, we then compiled all health care claims for three months prior to the date of initiation of therapy, and for six months subsequent to that date. Every nondrug claim was classified as either accident- or nonaccident-related on the basis of the physician-recorded ICD-9-CM diagnosis codes. Claims with any ICD-9-CM diagnosis code between 800-959 or 990-995 were considered to be accident-related; all other claims were considered nonaccident-related. Emergency visits were identified on the basis of accompanying information noting the type of service rendered (i.e., "emergency medical care").

Univariate Analysis

To examine the relation between benzodiazepine use and overall risk of accidental injury, we considered three outcomes: 1) the occurrence of any accident-related *emergency outpatient visit;* 2) the occurrence of any accident-related *hospital admission;* and 3) the occurrence of an accident-related *medical encounter of any type*. The frequencies of these events among benzodiazepine users and nonusers during the six-month period following initiation of therapy were determined.

To examine evidence of a temporal relationship between benzodiazepine use and risk of accidental injury, among users we compared the frequencies of accident-related medical encounters during months of presumed drug exposure to those during months of presumed nonexposure. A user was presumed to have been "exposed" to benzodiazepines during a given month if a pharmacy claim for one of these agents was observed in that month or the previous month.

Finally, to ascertain whether there is evidence of a relation between the number of benzodiazepine prescriptions filled and the risk of accidental injury, we compared rates of accident-related medical events among users according to their numbers of pharmacy claims for benzodiazepine agents during the six months following initiation of therapy. Two groups of users were defined—those who had only one pharmacy claim for a benzodiazepine agent and those who had three or more such claims—and we compared rates of accident-related medical events between them.

Comparisons of rates were expressed as ratios, or relative risks, and 95 percent confidence intervals were calculated by the Taylor-series method.[11]

Multivariate Analysis

To control for factors other than benzodiazepine use, we fitted a Cox proportional hazards model[12] and included as covariates age, sex, and the logarithms of total accident- and nonaccident-related medical care charges during the three months prior to therapy.

We used a similar proportional hazards model to compare the risk of accident-related medical encounters during months in which a user was presumed to have been exposed to benzodiazepines to all other months. Included in this model were a set of additional binary variables indicating, for each month during the six-month period of follow-up, whether a user was presumed to have been exposed to benzodiazepines in that month.

Finally, we used a similar model to compare outcomes between benzodiazepine users who filled three or more prescriptions for these agents and those who filled only one such prescription. Risks of each accident-related event were estimated as a function of the number of benzodiazepine prescriptions filled, age, sex, and the logarithms of total accident- and nonaccident-related medical-care charges during the three months prior to therapy.

Results

Profile of Benzodiazepine Users and Patterns of Benzodiazepine Use

Benzodiazepine users were more likely to be women than men (65.4 percent versus 34.6 percent), and more than one-half (53.5 percent) were less than 45 years of age. Approximately one-half (48.3 percent) of benzodiazepine users filled only a single prescription for one of these agents, 21.3 percent filled two prescriptions, 11.2 percent filled three prescriptions, and 19.2 percent filled four or more prescriptions over the six-month period of follow-up.

During the three-month period prior to the initiation of therapy, benzodiazepine users were twice as likely as nonusers (95 percent CI: .96, 4.44) to have at least one accident-related emergency outpatient visit (2.4 versus 1.2 per 1,000); 1.7 times as likely (95 percent CI: 1.11, 2.61) to have an accident-related hospital admission (7.2 versus 4.2 per 1,000); and 1.5 times as likely (95 percent CI: 1.29, 1.66) to have an accident-related medical encounter of any type (73.6 versus 50.2 per 1,000.

Accident-Related Care among Benzodiazepine Users and Nonusers

During the six-month period following the initiation of therapy, benzodiazepine users were significantly more likely than nonusers to require accident-related care (Table 1). Compared to nonusers, users were more than twice as likely to have had an accident-related emergency outpatient visit, about 1.6 times more likely to have experienced at least one accident-related hospital admission, and approximately 1.2 times more likely to have had at least one accident-related medical encounter of any type.

We examined rates of accident-related encounters among persons who had no accident-related care during the three-month period prior to the initiation of therapy. Unadjusted relative risks of accident-related events among benzodiazepine users were similar to those reported in Table 1.

TABLE 1—Risks of Accident-related Medical Encounters among Persons Who Were Prescribed Benzodiazepine Tranquilizers ("users") Compared to Those Who Were Not ("nonusers")

Accident-Related Medical Encounter	Monthly Rate per 1,000		Unadjusted Relative Risk (95% CI)	Adjusted Relative Risk* (95% CI)
	Users	Nonusers		
Any emergency outpatient care	1.06	.49	2.16 (1.35,3.50)	2.09 (1.27,3.42)
Any hospital admission	1.39	.88	1.58 (1.07,2.34)	1.27 (.84,1.90)
Any medical encounter	23.31	18.84	1.24 (1.14,1.35)	1.15 (1.05,1.26)

*Hazard ratio adjusted for age, sex, and pretreatment medical care utilization.

For emergency outpatient visits, the unadjusted relative risk was 2.18 (95 percent CI: 1.27, 3.77); for hospital admissions, it was 1.77 (95 percent CI: 1.13, 2.78); and for medical encounters of any type, it was 1.21 (95 percent CI: 1.10, 1.33). Controlling for age, sex, and health care utilization in the three months prior to the initiation of therapy did not change the excess risk of accident-related medical encounters among benzodiazepine users relative to nonusers appreciably (Table 1).

Accident-Related Care by Temporal Pattern of Benzodiazepine Use

Outcomes among benzodiazepine users were examined during 11,389 months of presumed drug exposure (i.e., months in which prescriptions for benzodiazepines had recently been filled) and 15,935 months in which they were presumed unexposed. A greater likelihood of accident-related medical encounters was observed during months of exposure (Table 2). Controlling for age, sex, and health care utilization in the three months prior to treatment, adjusted relative risks were somewhat lower than unadjusted ratios but remained excessive.

Accident-Related Care by Amount of Benzodiazepine Use

Benzodiazepine users who filled at least three prescriptions for these agents (n = 1,384) were more likely to have required accident-related care than those who filled only one such prescription (n = 2,200) (Table 3). Compared to users who filled one prescription, those who filled three or more prescriptions were about 2.4 times more likely to have had an accident-related emergency outpatient visit, and roughly 1.3 times more likely to have had an accident-related medical encounter of any type. The relative risk of an accident-related hospital admission was 1.5. Controlling for age, sex, and health care utilization during the three-month period prior to treatment did not change these risks substantially (Table 3).

Discussion

The results of this study suggest that the use of benzodiazepine tranquilizers increases the risk of accidental injury requiring medical attention. Emergency outpatient care, hospital admissions, and medical encounters of all types were more frequent among persons who were prescribed benzodiazepines than those who were not; among persons who were prescribed benzodiazepines, the likelihood of such care was higher during months in which such a prescription had recently been filled than during other months; and persons who filled three or more prescriptions for benzodiazepines over a six-month period had greater numbers of accident-related medical encounters than those who had filled only one such prescription. Increased risks of accident-related care remain even after controlling for the potentially confounding effects of age, sex, and prior differences in utilization.

TABLE 2—Risks of Accident-Related Medical Encounters among Persons Who Were Prescribed Benzodiazepine Tranquilizers during Months in Which Such a Prescription Was Recently Filled ("exposed") Compared to other Months ("unexposed")

Accident-Related Medical Encounter	Monthly Rate per 1,000		Unadjusted Relative Risk (95% CI)	Adjusted Relative Risk* (95% CI)
	Exposed	Unexposed		
Any emergency outpatient care	1.23	.94	1.31 (.63,2.70)	1.13 (.46,2.77)
Any hospital admission	1.84	1.07	1.73 (.91,3.27)	1.42 (.66,3.04)
Any medical encounter	31.87	17.19	1.85 (1.59,2.16)	1.28 (1.04,1.56)

*Hazard ratio adjusted for age, sex, and pretreatment medical care utilization.

TABLE 3—Risks of Accident-related Medical Encounters among Persons Who Filled Three or more Prescriptions for Benzodiazepine Tranquilizers ("scripts") Compared to Those Who Filled one such Prescription

Accident-Related Medical Encounter	Monthly Rate per 1,000		Unadjusted Relative Risk (95% CI)	Adjusted Relative Risk* (95% CI)
	Three or More Scripts	One Script		
Any emergency outpatient care	1.81	.76	2.38 (1.16,6.04)	2.64 (1.15,6.04)
Any hospital admission	1.57	1.06	1.48 (.70,3.13)	1.42 (.67,3.03)
Any medical encounter	27.70	21.52	1.29 (1.10,1.51)	1.30 (1.09,1.55)

*Hazard ratio adjusted for age, sex, and pretreatment medical care utilization.

We note that approximately one-third of the benzodiazepine users in our sample filled three or more prescriptions for these agents over a six-month period, and that these persons were at highest risk. Compared to persons who were not prescribed benzodiazepines, persons who filled three or more such prescriptions were 3.7 times (95 percent CI: 2.05, 6.68) more likely to have had an accident-related emergency outpatient visit (10.8 versus 2.9 per 1,000), 1.8 times (95 percent CI: 0.99, 3.21) more likely to have had an accident-related hospital admission (9.4 versus 5.3 per 1,000), and 1.5 times (95 percent CI: 1.30, 1.67) more likely to have had at least one accident-related medical encounter of any type (166.2 versus 113.0 per 1,000).

Our control group consisted of patients who received prescription drugs other than benzodiazepines, some of which may also affect the central nervous system. Our findings concerning the increase in risk of accidental injury associated with the use of benzodiazepines may therefore be conservative. Since we do not know whether persons who filled prescriptions for benzodiazepines in fact took any medication and, if so, how much they took and for how long, we may have overestimated drug exposure in our user group. Similarly, there may have been some exposure to these agents among our nonusers. While we excluded all persons with pharmacy claims for benzodiazepines from our nonuser group as well as those related by blood or marriage to these persons, we could not exclude those who had received these agents directly from their physician or those who had obtained these drugs illicitly. Our estimates of relative risk may therefore be conservative.

We considered the possibility that benzodiazepine users simply may be more accident prone than nonusers, due to differences in behavior, lifestyle, occupation, and so forth. We feel that this is unlikely, however; such factors could not account for the *temporal* association between benzodiazepine use and accident-related care that we observed among patients receiving these agents.

Since benzodiazepine tranquilizers often are prescribed for acute anxiety, we also considered the possibility that anxiety itself rather than the prescribed medication may cause users of these agents to be more accident-prone. Accordingly, we identified all persons who had claims for mental health services at any time during the 30 days prior to or following the initiation of benzodiazepine or nonbenzodiazepine therapy, but no such claims previously. When included as a covariate in our proportional hazards model, however, this variable was found to be uncorrelated with patients' risk of accident-related care, and was subsequently dropped. We note also that the results of controlled experiments lend credence to our finding that benzodiazepine use per se increases the risk of accident-related care.

We also considered the possibility that benzodiazepine users simply may be more likely than nonusers to seek medical treatment for minor injuries. Benzodiazepine users have been found to have higher rates of medical encounters unrelated to accidents than nonusers,[8] which suggests that users might be prone to seek professional care more often than nonusers. Again, the temporal association between the filling of prescriptions for benzodiazepines and accident-related encounters cannot readily be explained by differences in care-seeking behavior. Also, the excess in accident-related care among persons who received such prescriptions relative to those who did not remained even after we controlled for prior differences in patterns of health care utilization. Finally, while a greater number of outpatient visits might be related to differences in propensity to seek care, an excess of accident-related hospital admissions among benzodiazepine users can less plausibly be attributed to patients' discretion.

The foremost limitation of our study is that we could observe neither benzodiazepine use nor the occurrence of accidental injuries directly. We inferred the former from the presence in patients' records of pharmacy claims for these agents. We inferred the latter from the presence of nondrug claims with physician-recorded ICD-9-CM diagnosis codes indicating injury as the reason for rendering care, and the assumption that such injuries were accidental and not self-inflicted. To the extent that plan members may have received prescription drugs from other sources, we may have incorrectly identified some persons as nonusers who in fact used benzodiazepines. While it is also possible that some study subjects were treated for injuries without corresponding claims being submitted to the plan, we believe that this is unlikely. Also, there is no apparent reason why such out-of-plan care should be more frequent among persons who were prescribed benzodiazepines than among those who were not, or vice versa.

A more likely problem deriving from the use of claims data is that some of the accident-related care that we observed in the six-month period following initiation of therapy may in fact have been for follow-up treatment of injuries that occurred prior to therapy. The benzodiazepine user group, for example, may have included persons with pre-existing back strain, for which benzodiazepines are sometimes prescribed. Similarly, the benzodiazepine non-user group, which was selected from among all persons with nonbenzodiazepine drug claims, may have included patients who were prescribed analgesics for control of prior accident-related pain. We note, though, that when we compared rates of accident-related encounters among persons who had no such care during the three-month period prior to therapy, our results were largely unchanged.

There are important limitations inherent in any study that uses claims data. We note, however, that data bases of the type we have employed are being used increasingly to study outcomes of care: health care claims data, for example, recently have been used to monitor the incidence of birth defects among patients receiving the acne medication, isotretinoin,[13] and to estimate the risks of mortality and reoperation following prostatectomy.[14]

Despite possible limitations, we believe that our study has several important implications. Our findings suggest that the use of benzodiazepine tranquilizers may increase the risk of accidental injury. They therefore corroborate those of previous studies. The conditions for which these agents are prescribed, however, need and deserve treatment. Accordingly, patients should be advised of the potential risks associated with the use of these agents. Also, when appropriate, alternative therapies might be considered, particularly for persons who must operate machinery or a motor vehicle, those who would use alcohol, and those who may require an extended period of therapy.

A Case-Control Study of the Effectiveness of Bicycle Safety Helmets in Preventing Facial Injury

Diane C. Thompson, MS, Robert S. Thompson, MD, Frederick P. Rivara, MD, MPH, and Marsha E. Wolf, PhD

Abstract: In a case-control study we sought to assess the potential effectiveness of helmets in preventing facial injuries. Our study included 212 bicyclists with facial injuries and 319 controls with injuries to other body areas, who were treated in emergency rooms of five Seattle area hospitals over a one-year period. Using regression analyses to control for age, sex, education and income, accident severity, and cycling experience we found no definite effect of helmets on the risk of serious facial injury (odds ratio 0.81; 95 percent confidence interval = 0.45, 1.5), but protection against serious injuries to the upper face (odds ratio 0.27; 95% CI = 0.1, 0.8). No protection was found against serious injuries to the lower face. The independent effect of helmet use on facial injury was difficult to isolate due to the association of head and facial injuries.

Our results suggest that bicycle helmets as presently designed may have some protective effect against serious upper facial injuries. (*Am J Public Health* 1990;80:1471–1474.)

Introduction

Recently we showed that bicycle helmets reduce the risk of head injury by 85 percent.[1] Facial injuries in the population we studied occur at nearly identical rates (43 per 100,000) as head injuries (45 per 100,000) in bicyclists and can be serious. Bicycle crashes were found to account for 7.1 percent of all facial fractures treated in a large Swedish University hospital over a three-year period.[2]

There are no reported studies on the effectiveness of bicycle helmets in altering the risk of facial injury. Several reports suggest facial injuries are decreased in helmeted motorcyclists and moped riders,[3–5] but motorcycle and moped helmets generally have face pieces whereas traditional bicycle helmets have no face pieces.

The present case control study describes facial injuries resulting from bicycle crashes and evaluates the effect of bicycle helmets on the risk of these injuries.

Methods

Data for the present study were collected as part of a case control study of head injuries resulting from bicycle crashes. The methods have been described in detail elsewhere.[1] In brief, the study was conducted by emergency room surveillance at five major Seattle area hospitals: the Central and Eastside Hospitals of Group Health Cooperative (GHC) of Puget Sound, a large staff model health maintenance organization; University Hospital of the University of Washington; Harborview Medical Center, a regional Level I trauma center; and Overlake Hospital, a community hospital caring for a large proportion of the trauma to the east of Seattle. The records of the medical examiner's office were examined for the study period to ascertain any cyclist deaths occurring at the scene of a crash.

Definitions

Cases were defined as bicyclists who had suffered a facial injury in a bicycle crash and who sought treatment at the emergency room of one of the five study hospitals during the one-year study period December 1, 1986 through November 30, 1987. Facial injury was defined as injury to the area of the face beginning with the eyebrows and extending to the chin, mouth, and teeth. Injuries to the forehead and skull were classified as head injuries and those without concurrent facial injuries were excluded from the facial injury case group.

To address possible overascertainment of minor facial injuries among those individuals who seek care for more serious concomitant injuries, such as head injuries, we used only cases with more serious facial injury, defined as lacerations, fractures of the facial bones, and fractures of the teeth.[6,7]

Patients with serious facial injury were divided into two groups: the upper facial region included the midface, nose and eye/orbit area, the region where helmets would be expected to have the greatest protective effects; the lower facial region included the mouth and chin.

The case groups formed by the above definitions contained bicyclists who had injuries to both the head and facial regions and those who had face injury without concomitant head injuries. It is difficult to separate the possible effect of an intervention (helmet) on different injuries particularly when there is close anatomical association (head and face). We felt the most appropriate definition of a facial injury case group would include all crashing cyclists who sustained a facial injury regardless of the presence of injuries to other areas of the body.

The main comparison group (N = 319) was composed of bicyclists who sought care at the same five emergency rooms for bicycle related injuries other than to the face or head. Head injuries were excluded from the control group, since a cause and effect relationship between bicycle safety helmet use and head injury exists.

A population-based control group (N = 558) consisting of GHC member bicyclists who had experienced a crash in the last year was employed in ancillary analyses. Those under 15 years of age in this control group had significantly higher helmet usage rates at the time of the cycle crash (21.1 percent)

as compared to the same age group from the emergency room controls (5.9 percent).[1]

Data Collection

As described elsewhere[1] emergency room cases and controls were identified by weekly surveillance of emergency room logs. All cases and controls were mailed an introductory letter and study consent form explaining the purpose of the study. Detailed questionnaires described earlier[1] were sent to each person with telephone follow-up of nonrespondents. Medical data on injuries was obtained by abstracting the emergency room records.

Statistical Analysis

The statistical package SASPC was used to evaluate descriptive information and prepare crude risk estimates. Unconditional logistic regression techniques were used to estimate the relative risk of facial injury associated with helmet use and to control for multiple confounding factors.[8] The Egret software package was used to carry out logistic regression. The Mantel Haenszel procedure was used to compute age stratified odds ratios in instances where cell sizes were small or included zero.[9]

Results

Seven hundred seventy-six people were treated in the five hospital emergency rooms for bicycling injuries during the study period. Two hundred fifty-six individuals had facial injuries and were potential cases; 368 had injuries involving other parts of the body and were potential emergency room controls. An additional 151 emergency room controls with head injuries were excluded from the analyses. Overall response rate to our questionnaire was 85.0 percent (82.8 percent of cases and 86.7 percent of controls) resulting in 212 cases and 319 emergency room controls available for analysis.

The type and location of the injuries are presented in Table 1. Of the 212 individuals with facial injuries, 136 (64.2 percent) had injuries to one area of the face, 53 (25 percent) had injuries to two areas of the face, 18 (8.5 percent) had injuries to three areas, and 2.3 percent had injuries to four or five areas of the face.

There were three deaths in the study, all of whom were adults with severe head injuries in addition to facial injuries. No bicyclists died at the crash scene.

Demographic Characteristics and Helmet Use of Cases and Controls

As shown in Table 2, cases were younger than controls. There were no important differences between case and control groups by sex, education of head of household, or household income. The distribution of helmet use at time of crash differed between cases and controls. Individuals with any type of facial injury were less likely to have been using helmets at the time of the crash than the control group. There was substantially lower helmet usage among the youngest cyclists. Helmet ownership rates followed a pattern similar to usage rates. Approximately 90 percent of the helmets were of the hardshell variety.

TABLE 1—Type and Location of Facial Injuries Experienced (N = 212 individuals)

	Number and Type of Injury		
Location	Abrasion/Contusion	Laceration	Fracture
Eye/Orbit	23	8	4 (orbit)
Nose	20	12	4
Midface	72	18	7 (zygoma)
Mouth	12	20	33 (teeth & maxilla)
Chin	29	52	4 (mandible)

Notes: Injuries to one area/location of the face are not mutually exclusive of injuries to other areas.

Types of injuries at each location are mutually exclusive.

Crash Characteristics of Cases and Control

Table 3 portrays various aspects of crash severity. Cases were more likely to have hit a stationary obstacle than were controls. Damage to the bicycle was somewhat more frequent for cases. Collisions with motor vehicles, self-reported bicycle speed at the time of crash, and the type of surface impacted was similar for both cases and controls. Cycling experience (kilometers ridden per week, data not shown) was significantly greater in control group.

Risk of Facial Injury Adjusted for Covariates

The focus of our study was to examine the association between bicycle safety helmet use and a set of successively more restrictive and biologically plausible outcomes: all facial injuries, serious facial injuries, and serious upper facial injuries.

The following variables were evaluated using logistic regression analyses: age, sex, cycling experience (kilometers per week cycled), severity (cause of crash, damage to cycle), education, income, and hospital. Only age, as a covariate, accounted for marked changes in computed odds ratios; therefore, we chose to use the simplest model adjusting only for the effects of age. There appeared to be no definite association between safety helmet use and all facial injuries (odds ratio 0.69; 95% CI = 0.41, 1.1) or serious facial injuries (odds ratio 0.81; 95% CI = 0.45, 1.5). When cases with only serious upper facial injuries were examined, a protective effect emerged (odds ratio 0.27; 95% CI = 0.1, 0.8).

Independent Effect of Helmet Use

The analysis of the association between bicycle safety helmet use and facial injury is difficult because some of the association demonstrated between helmet use and facial injury risk is due to the additional association of facial injury and head injury.

Ninety-eight (46.2 percent) of the 212 facial injury cases had a concurrent head injury; 48 (37.8 percent) of the 127 cases with serious facial injury (lacerations, fractured bones or teeth) had a concurrent head injury. The serious facial injury group included a total of 44 individuals with injuries to the upper facial region and 99 individuals with injuries to the lower face; 16 of those individuals had injuries to both regions of the face. Concurrent head injury was present in 27 (61.4 percent) individuals with serious upper facial injury, and in 31 (31.3 percent) of those with serious lower facial injuries.

A series of ancillary analyses were undertaken to attempt to isolate the effect of helmets on facial injuries. The age-adjusted odds ratio for all cases with concurrent head and face injuries (N = 98) was 0.4 (95% CI = 0.18, 0.83). However, when only serious lower facial injuries were examined, the age-adjusted odds ratio was 1.0 (95% CI = 0.6, 2.0) for cases with facial injury only (N = 114) 1.1, (95% CI = 0.57, 1.97).

Finally, we performed analyses utilizing the population control group of GHC cyclists experiencing a crash in the prior year to address the question of protective effect in crashing cyclists in general. Protective effects were found for

serious upper facial injury; the age-adjusted odds ratio was 0.14 (95% CI = 0.04, 0.47). When facial injuries only were used as the case group, the odds ratio was 0.5, (95% CI = 0.3, 0.9).

Discussion

The results of this study are consistent in suggesting a protective effect of bicycle safety helmets on serious injuries of the upper facial region (lacerations and fractures of the midface, nose, eye/orbit). This conclusion has biological plausibility. The precise magnitude of the protective effect cannot be estimated, since it was not possible to completely disentangle protective effects against facial injury from the effects of head injury occurring concurrently in the same individual.

The significant association of head trauma and facial injury requires careful case and control definition. Head-injured patients were excluded from the emergency room control group because the head injury is directly related to the exposure (helmet use).[1] Their inclusion would have resulted in an underestimation of the protective effect of helmets on facial injuries by selecting for unhelmeted controls. This would be analogous to excluding individuals with lung cancer from the control group in a study of the association of smoking with heart disease.

The most representative facial injury case group is composed of all cyclists with facial injuries including those with injuries to the head or other portions of the body. Equal ascertainment of facial injuries among injured cyclists is important. The presence of a concurrent head injury increases the likelihood that an injured individual seeks medical attention and thus becomes a case. Since head injury is so strongly associated with the lack of helmet use, such a bias can result in an overestimation of the protective effect of helmets by potentially increasing the number of unhelmeted cases. Ascertainment bias was minimized by defining a case group with serious facial injury, i.e. injury serious enough to necessitate medical attention independently of the presence of a head injury. This analysis suggests no association between helmet use and the risk of facial injuries.

We attempted in the analysis to determine the independent effect of bicycle safety helmets on facial injuries. Although there was no effect of helmets on facial injury alone (cases with concurrent head injury excluded) when the emergency room controls were used as comparison, use of the same case group with the population-based control group suggested some protective effect of helmet use (odds ratio 0.5; 95% CI = 0.3, 0.9). This is a more conservative analysis since individuals with head injury and thus low chance of helmet use were excluded. If a helmet effect is present, one would expect to show this effect using the population controls as the comparison group. This is a less seriously injured group of cyclists and has a higher rate of helmet use than the emergency room controls. The demonstration of some protective effect with facial injuries only is important, since it indicates effect on facial injury separate from head injury effects.

Current bike helmets do not have a face bar; consequently one would expect little or no protection against injuries to the lower face. The negative results for serious lower facial injury lend credence to the positive protective effect found for serious upper facial injury.

The strong association between helmet use and decreased risk for serious upper facial injuries is likely explained by a combination of factors: the association of upper facial injuries with head injuries, (61.4 percent of those with serious upper facial injuries) and an actual protective effect of helmets for upper facial injury.

A potential limitation of this study is that unmeasured factors not taken into account in our analysis may have placed controls at lesser risk for striking their faces at the time of the crash.

In conclusion, our study suggests that bicycle helmets as presently designed have little or no effect on the overall risk of facial injury, but appear to provide some protection for serious upper facial injuries. The magnitude of this effect is not precisely quantifiable. This study also illustrates the methodologic problems of isolating exposure or intervention effects on one injury type when multiple simultaneous injuries result from a single event. This problem is inherent to injury research, but much less likely in cancer or cardiovascular investigations.

ACKNOWLEDGMENTS

We are indebted to the Emergency Department staffs at Central and Eastside Group Health Cooperative of Puget Sound. University of Washington, Overlake Medical Center and Hospital, and the Harborview Trauma Registry for their help in completion of this study.

Certain individuals played a significant role in the success of this project: At Group Health, Travis Abbott, Roy Farrell, Richard Watkins, John Walter, Mark Barros, Lynn Bollinger, Judith Droullard, Sandra Howard, Katherine Hubenet, Judie Wischman; at the University of Washington, Mickey Eisenberg; at Harborview, Elizabeth Mueller, Marlis Dixon, Susan Pilcher, Rosalie Wendt; at Overlake, Jack Cilberti, Geri Dykman, and Elizabeth Reid.

We are particularly grateful for the expert help of Gene Hart as computer consultant and Ric Chandler as project research assistant. We gratefully acknowledge critical manuscript review by multiple colleagues particularly Louis Grothaus and William Barlow.

Special thanks to Cheryl Pernack for her assistance with data collection and preparation of this manuscript.

Association of Hepatitis B Surface Antigen and Core Antibody with Acquisition and Manifestations of Human Immunodeficiency Virus Type 1 (HIV-1) Infection

RACHEL E. SOLOMON, MHS, MARK VANRADEN, MA, RICHARD A. KASLOW, MD, MPH, DAVID LYTER, MD, BARBARA VISSCHER, MD, HOMAYON FARZADEGAN, PhD, AND JOHN PHAIR, MD

Abstract: We examined the associations between seropositivity for hepatitis B virus (HBV) with the presence or development of antibodies to human immunodeficiency virus (HIV-1) and with HIV-1 induced T-helper lymphocyte deficiency or acquired immunodeficiency syndrome (AIDS). Serologic data on HBV and HIV-1, cytometric enumeration of CD4$^+$ lymphocytes, clinical events (AIDS by Centers for Disease Control criteria) and hepatitis B vaccination histories were available on 4,498 homosexual participants in the Multicenter AIDS Cohort Study. Men were classified as to previous infection with HBV and prevalent or incident infection with HIV-1. Although there was an association between seropositivity for HBV infection and HIV-1 infection at enrollment (odds ratios anti-HB$_c$ 2.6; HB$_s$Ag 4.2), the relation between HBV seropositivity and subsequent seroconversion to HIV-1 was weaker (odds ratios 1.3 and 1.6). HIV-1 seroconversion was also associated with a history of certain other sexually transmitted diseases, but predisposing sexual practices did not account for the association between HBV and HIV-1 infection. Seropositivity for HBV infection at entry was not related to initially low or more rapid subsequent decline in T-helper lymphocyte counts and was not associated with an increased incidence of AIDS during 2.5 years of follow-up. History of vaccination against HBV did not appear to decrease susceptibility to HIV-1 infection or to subsequent progression of immunodeficiency. We conclude that prior HBV infection is unlikely to be specifically associated with acquisition of HIV-1 infection and is unrelated to more rapid progression of HIV-1-induced immunodeficiency. (*Am J Public Health* 1990; 80:1475–1478.)

Introduction

Approximately 300,000 new cases of hepatitis B virus (HBV) infection occur every year in the United States alone.[1] Before the spread of acquired immunodeficiency syndrome (AIDS) resulted in altered patterns of sexual behavior, an estimated 60 percent of homosexual males demonstrated serologic evidence of previous hepatitis B infection as measured by antibody to hepatitis B core antigen (anti-HB$_c$), and approximately 5 percent were chronic carriers of hepatitis B surface antigen (HB$_s$Ag).[2] Homosexual males were at 10 to 15 times greater risk of prior HBV infection than men in the general population.[2] Consequently, even before human immunodeficiency virus, type 1 (HIV-1) was established as the cause of AIDS there was considerable interest in a possible direct or cofactorial role for HBV in the AIDS epidemic.[3–5]

In most epidemiologic studies, homosexual men have experienced high rates of infection with both HBV and HIV-1.[6–9] Detailed cross-sectional analysis of men who enrolled in the Multicenter AIDS Cohort Study (MACS), a prospective study of HIV-1 infection in homosexual men, demonstrated that the close association between detectable anti-HB$_c$ or HB$_s$Ag and seropositivity for HIV-1 infection was highly significant and independent of sexual practices commonly predisposing to both infections.[10] Observations of this kind, coupled with the recent description of an effect of the hepatitis B virus protein X on HIV-1 replication in vitro,[11,12] have encouraged speculation about concurrent HBV as a codeterminant for infection or disease with HIV-1. We report here an analysis of possible relations of prevalent HBV infection (anti-HB$_c$ or HB$_s$Ag) to the acquisition and to manifestations of HIV-1 infection in homosexual men.

Methods

The MACS enrolled 4,954 homosexual males without AIDS as defined by CDC criteria[13] in four metropolitan US areas[9,10] from April 1984 through April 1985. The study centers are located in Baltimore, Maryland (Johns Hopkins University), Chicago, Illinois (Howard Brown Memorial Clinic/Northwestern University), Los Angeles, California (University of California), and Pittsburgh, Pennsylvania (University of Pittsburgh). At both entry and follow-up visits interviewers administered a standardized questionnaire, through which we obtained a demographic profile, past medical history, drug and medication history, history of hepatitis B vaccination, psychological assessment, and sexual behavior data.

Serum specimens taken from all men at entry were examined for antibodies to HIV-1, for HB$_s$Ag, and for anti-HB$_c$; at each six-month follow-up visit participants were tested for antibodies to HIV-1. Testing for anti-HIV-1 was performed by enzyme-linked immunoassay (EIA) using licensed, commercially available reagents (DuPont and Genetic Systems), and positive results on the EIA were confirmed by immunoblot assays. Standard EIA or radioimmunoassay techniques using commercially available kits (Abbott Laboratories, Inc.) were used to test for prevalent HBV infection (defined as detectable HB$_s$Ag or anti-HB$_c$). The ordinarily small number of men who may have had antibodies to HB$_s$Ag only were thereby classified as HBV-seronegative. Lymphocytes were phenotyped using standard flow cytometric techniques, as previously described for the MACS,[9] at each of the first three visits for all men and at all subsequent visits for HIV-1-seropositive men, as well as for a subset of HIV-1-seronegative men.

This paper, submitted to the Journal December 18, 1989, was revised and accepted for publication May 21, 1990.

In our analysis of the effects of hepatitis B infection on HIV-1 infection and accompanying immunodeficiency, we excluded 287 men whose initial serologic status (for HBV or HIV-1) or hepatitis B vaccination status was unknown. Of the remaining 4,667 participants, 531 reported having received hepatitis B vaccine prior to entry, and 362 of those vaccinated were known to be serologically negative for HB$_s$Ag and anti-HB$_c$. These men were analyzed separately because of the diminished likelihood of past or current HBV infection.

To examine the possible relation between prior HBV infection and the degree of cellular immunodeficiency, we compared HBV-infected and -uninfected HIV-1-seropositive men for differences in their numbers of CD4$^+$ and CD8$^+$ lymphocytes at entry and differences in the mean changes in those numbers during 2.5 years of follow-up. Slopes of decline in CD4$^+$ cells were calculated by the least squares method, and differences between slopes for the HBV-infected and -uninfected men were compared with a standard t or a Wilcoxon rank sum test. In addition, a life table analysis of the first 2.5 years of follow-up in HIV-1-seropositive MACS participants was performed to examine the effect of prior HBV infection on the incidence of AIDS.

Associations between outcomes and potential risk factors were individually estimated with odds ratios (OR). Life tables and associated log rank tests were calculated by standard computerized statistical packages (SAS Proc Survfit and Proc Survtest). For cross-sectional multivariate analyses, multiple logistic regression techniques were employed using a standard package (BMDPLR), and adjusted ORs were computed from the coefficients derived from the regression model. For prospective analyses, time-dependent Cox proportional hazards models were applied using a standard package (SAS Proc PHGLM).

Results

The 2,826 MACS participants who were unvaccinated against HBV and had serologic evidence of prior or current HBV infection at entry differed from their 1,310 HBV-seronegative counterparts in HIV-1 seroprevalence at entry and in rates of HIV-1 seroconversion during 6 and 24 months of follow-up (Table 1). For further analysis of the relation between hepatitis B and HIV-1 infections present at baseline, multiple logistic regression was used to adjust for a number of known or suspected baseline correlates of anti-HIV-1 (Table 1). The presence of HB$_s$Ag and/or anti-HB$_c$ remained independently correlated with the presence of HIV-1 at entry (adjusted OR: presence of HB$_s$Ag ± anti-HB$_c$, 4.2; presence of anti-HB$_c$ only, 2.6) (Table 1). As previously reported from the MACS,[10] other sexually transmitted infections such as gonorrhea, anogenital herpes, syphilis, cytomegalovirus infection and others, taken singly or in combination, also showed strong relations (ORs = 1.7–4.1) to baseline HIV-1 seropositivity (data not shown).

In the analysis of the relation between baseline HBV seropositivity and subsequent HIV-1 seroconversion among the 2,421 unvaccinated HIV-1-seronegative men, after adjustment for other potentially related variables, the presence of HB$_s$Ag and of anti-HB$_c$ at entry was less strongly but still related to HIV-1 seroconversion in 83 men who developed HIV-1 antibodies during the six-month follow-up and in 181 who developed HIV-1 antibodies during the 30-month follow-up (Table 1). The analyses also suggested independent relations of magnitude similar to those seen in the cross-sectional analyses (OR = 1.4–1.9) between HIV-1 seroconversion and a history of one or more sexually transmitted infections other than HBV.

To determine the possible role of previous HBV infection in the progression of quantitative T-lymphocyte deficiency, we analyzed T-lymphocyte phenotypes in unvaccinated HIV-1-seropositive participants as follows: 1,348 men with six months, 1,131 men with 18 months, and 929 men with 30 months of follow-up data. The presence of HB$_s$Ag or

anti-HB$_c$ showed no consistent relation either to mean initial T-helper (CD4$^+$) and T-suppressor (CD8$^+$) cell counts or to any change in counts of these cell types during the follow-up periods. The absence of any effect on mean decline in CD4$^+$ cell counts persisted after adjustment for initial count. During the entire follow-up, among unvaccinated men the mean six-month declines in counts were: all HB$_s$Ag+ = .0391 cells × 10^9/L; HB$_s$Ag−, anti-HB$_c$+ = .0452 cells × 10^9/L; and HB$_s$Ag−, anti-HB$_c$− = .0421 cells × 10^9/L (p = NS). Comparable analyses were performed on T-lymphocyte data available for approximately 18 months from HIV-1-seronegative men, and no relations were found.

During the first 2.5 years of follow-up, AIDS developed in 198 of the 1,532 participants who had HIV-1 antibodies at entry and had not received hepatitis B vaccine. The cumulative 2.5 year life table incidence of AIDS in these men was the same whether serologic evidence of HBV infection was present or absent at entry (Figure 1). In particular, neither men who were positive for HB$_s$Ag at baseline nor men who were negative for HB$_s$Ag but positive for anti-HB$_c$ had a higher incidence of AIDS than men who were negative for both HB$_s$Ag and anti-HB$_c$. The results were unchanged when stratified by number of CD4$^+$ cells at entry.

To assess the possible effects of HBV vaccine on susceptibility to HIV-1 infection, we analyzed HIV-1 seroconversion rates in HIV-1-negative, HB$_s$Ag-negative, anti-HB$_c$-negative vaccine recipients versus serologically identical non-recipients. Among 1,320 such participants who had completed at least six months of follow-up, men with and without a history of vaccination reported similar high-risk sexual practices and seroconverted at similar rates during the next six and the next 24 months. In the 24-month period, life table rate of HIV-1 seroconversion was not substantially different between vaccinees (n = 274, 6.0%) and nonvaccinees (n = 1,046, 4.7%) (95% confidence interval of difference: −1.9, 4.5). The slightly higher seroconversion rate in vaccinees is consistent with their slightly higher frequencies of such indicators of high risk as the numbers of sexual partners in the recent past and the proportion of men who had had at least one sexually transmitted infection (data not shown).

At entry, HIV-1-seropositive men with a history of HBV vaccination did not demonstrate a low CD4$^+$ cell count more frequently than serologically identical unvaccinated men. During the 2.5 years of follow-up, the vaccinated men showed a slightly more rapid decline in their CD4$^+$ counts. The difference in mean slopes between vaccinated men (−.075 cells × 10^9/L per six months) and unvaccinated men (−.042 cells × 10^9/L per six months) fluctuated with the statistic examined (p = .044 by t test, p = .017 by the nonparametric Wilcoxon test). During the first 2.5 years of follow-up of initially HIV-1 seropositive men, the life table incidence of AIDS was about 15 percent in those who were HBV-seropositive (Figure 1). In the same interval the incidence was about 20 percent in those who were HBV-seronegative with or without a history of HBV vaccination.

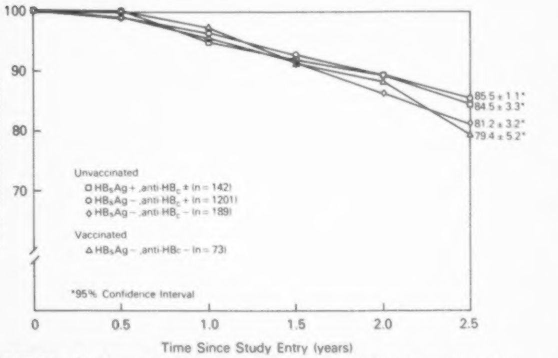

FIGURE 1—Incidence of AIDS among 1605 Initially HIV-1 Seropositive Men, According to Hepatitis B Virus Serologic Status at Baseline

Discussion

Recent evidence that HBV can infect lymphocytes and produce a protein capable of activating HIV-1[11,12] has renewed interest in the early hypothesis that HBV influences susceptibility to or progression of infection with HIV-1.[14,15] Previous studies including our own[10] have demonstrated strong associations between the presence of HIV-1 antibodies at study entry and previous or persistent infection with several sexually transmitted infections, including HBV. Our current investigation confirmed these cross-sectional observations; however, the more powerful longitudinal analysis has provided only meager evidence that previous HBV infection is truly a cofactor for acquisition of infection with HIV-1. We found that HBV infection at baseline was weakly correlated with HIV-1 seroconversion during the next six and the next 24 months. This relation could imply that past or current HBV infection facilitates HIV-1 infection. Since the relation to seroconversion in both time intervals occurred among individuals positive only for anti-HB$_c$, if there is a true relation, it does not appear to depend closely on the presence of circulating HB$_s$Ag. Although the data could be interpreted as indicative of a causal relation, considering the weakness of the association, we believe that other explanations must be considered equally plausible. One alternative explanation would be that HBV is but one of several sexually transmitted infections nonspecifically capable of facilitating establishment of HIV-1 infection, for example by "priming" T-lymphocytes for penetration or viral replication. Our analyses demonstrated independent relations of similar magnitude between several other sexually transmitted diseases and HIV-1 seroconversion. However, such multiple interrelations could be taken as evidence against any causal contribution of HBV.

To allow for possible temporal variations in the appearance of HIV-1 antibody, we further adjusted for the timing of HIV seroconversion by excluding men who seroconverted early in the follow-up period (within nine months of the baseline evaluation). This did not alter the association between anti-HB$_c$ seropositivity and HIV-1 seroconversion.

Although HBV may persist among persons expressing anti-HB$_c$ in the absence of HB$_s$Ag, a causal relation might have been more readily demonstrable among HB$_s$Ag-positive men. There was no clear evidence of such a causal relation to HIV-1 seroconversion. The absence of this relation was not likely due to the small number of men in this group: the power to detect a difference of two-fold or greater between them and all HB$_s$Ag-negative men was 80 percent.

Our observation that the HIV-1 seroconversion rates were comparable in vaccinated and in unvaccinated seronegative men argues against a protective effect of vaccine and against such a causal role for HBV. A few participants may have erroneously reported HBV vaccination or overestimated its completeness, but it is highly unlikely that misclassified vaccination experience explains these findings.

Our investigation provided no evidence that infection with HBV hastens the appearance of the major immunologic or clinical manifestations of HIV-1 infection. We found no firm associations between positive HBV serology and either altered T-cell phenotype distribution at the time HIV-1 seropositive men entered the study or declining numbers of T-helper cells during the next 24 months. Somewhat divergent results have been reported from the few other studies of the effects of HBV infection on T-cells[16–19] or on clinically significant immunodeficiency[20] in HIV-1-seropositive men. The divergence of findings could be due to the small size of the other studies or to differences in clinical settings, types of patients (i.e. heterosexual vs homosexual) or relative stages of HIV-1 infection. The apparent protection from progressive immunodeficiency in HIV-1-seropositive homosexual male HB$_s$Ag carries in San Francisco[20] was of borderline significance, and the analysis used in that study may not have fully accounted for age, the timing of HIV-1 infection or other factors among the HB$_s$Ag carriers. Our investigation also failed to demonstrate any association, before or after stratification by initial CD4$^+$ cell count, between HBV serologic status and subsequent development of AIDS.

A history of HBV vaccination was not related to altered T-helper lymphocyte counts at entry and probably not related to the slightly more rapid decline in counts subsequently. Our findings, like those of Stevens, *et al*,[20] and others, also suggested that hepatitis B vaccination neither enhances nor retards the development of AIDS. However, our ability to detect an effect of vaccination was limited by the number of vaccinees available for study.

In summary, this prospective investigation of a large number of homosexual men has provided insufficient epidemiologic evidence for and some evidence against the idea that prior or persistent HBV infection facilitates the acquisition of infection with HIV-1, no indication that past or concurrent HBV infection alters progression of HIV-1-induced immunodeficiency, and no suggestion that HBV vaccination in any way protects against either acquisition or progression of HIV-1 infection.

Death in Prison: Changing Mortality Patterns among Male Prisoners in Maryland, 1979–87

MARCEL E. SALIVE, MD, MPH, GORDON S. SMITH, MB, CHB, MPH, AND T. FORDHAM BREWER, MD, MPH

Abstract: The leading causes of death (rate per 100,000 prisoner-years) in Maryland state prisons for the period 1979–87 were circulatory system disease (59), suicide (40), and homicide and legal intervention (30). Acquired immunodeficiency syndrome (AIDS) became the leading cause of death in 1987. Homicides declined after 1980; drug overdose deaths peaked in 1981 and later disappeared. Male inmates have 39 percent lower all-cause death rates than the general population of Maryland after adjustment for age and race. (*Am J Public Health* 1990; 80:1479–1480.)

Introduction

Growing concern with the quality of prison health care has led several groups, notably the American Public Health Association, to develop standards of care for the incarcerated.[1] Despite the recognition that outcomes, including mortality, are useful indicators of quality of care in hospitals[2] and potentially prisons, prison standards do not require routine monitoring. Of over 500,000 inmates in state and federal prisons, 915 males died in the year ending June 1987.[3] National criminal justice statistics[3,4] merely group by type of death, and do not compute rates, make comparisons, or follow trends. Earlier studies[5,6] suggest that inmates have lower mortality than the general population. Descriptive studies have been reported from jails[5,7–10] but not from state prisons where inmates have longer sentences.

This study was designed to: investigate deaths among inmates in the Maryland prison system, examine trends, and compare inmate mortality with that of the general population.

Methods

All male deaths of Maryland state prisoners between January 1, 1979 and December 31, 1987 were studied. Maryland prisons house those persons convicted and sentenced to at least one year; the average stay is 40 months.[11,12] Females comprise only 4 percent of inmates, and were excluded. The prison management information system provided prisoner characteristics. Causes of death obtained from death certificates were classified by nosologists according to the International Classification of Diseases (ICD), 9th edition.[13] Deaths due to illicit drug overdose had been inconsistently classified; for the study they were grouped as unintentional poisoning (ICD E850–E858).

Annual and cause-specific death rates were calculated using prison census figures.[11,12] Indirect standardization used age- and race-specific death rates from Maryland[12,14–16] to calculate expected deaths and standardized mortality ratios (SMR). The 95 percent confidence interval (CI) of the SMR was computed.[17]

Results

Between 1979 and 1987, 204 male inmates died during 93,445 prisoner-years (crude mortality rate 218 per 100,000 prisoner-years). Of the deaths, 140 were from natural causes, 37 suicides, 16 illicit drug overdoses, 9 other unintentional injuries, and two undetermined (Table 1). Leading causes of death (rate per 100,000 prisoner-years) were circulatory system disease (59), suicide (40), homicide and legal intervention (30), malignant neoplasms (28), and unintentional injuries (25).

All-cause mortality peaked in 1980–81 and has since declined paralleling external causes (Figure 1). The natural-cause death rate remained relatively constant, although individual cause rates varied, especially for circulatory system diseases (data available from author on request). Infectious disease death rates were zero until 1984 when they increased rapidly, largely related to human immunodeficiency virus (HIV) infection, and became the leading cause of death in 1987 (65 per 100,000). Other natural causes of death occurred at steady rates. Illicit drug overdose accounted for a rise in external cause death rate that peaked in 1981 (data available from author on request). Homicide and legal intervention deaths had a slight peak in 1980–81 and decreased thereafter. Only one death was due to motor vehicles.

When compared with the Maryland general population,

TABLE 1—Comparison of Mortality among Male Prisoners (1979–87) with That of Men in the Maryland General Population (1983) for Major Causes of Death

	Number of Deaths			
Cause of Death (ICD Code)	Observed	Expected	SMR*	(95% CI)
Infectious and parasitic (001–139)	12	6.1	197	(114, 366)
Malignant neoplasms (140–208)	26	53.9	48	(33, 73)
Endocrine and metabolic (240–279)	1	4.6	22	(1, 121)
Circulatory system (390–459)	55	76.8	72	(54, 93)
Respiratory system (460–519)	9	8.6	105	(48, 199)
Digestive system (520–579)	5	11.4	44	(14, 103)
Genitourinary system (580–629)	3	3.3	90	(19, 264)
External causes (E800–E999)	88	119.4	74	(59, 91)
Unintentional injuries (E800–E949)	23	48.6	47	(23, 87)
Suicide (E950–959)	37	20.1	184	(130, 253)
Homicide and legal intervention (E960–E978)	28	47.5	59	(39, 85)
Other causes of death (290–239, 280–389, 630–799)	5	38.6	13	(4, 30)
All causes	204	334.2	61	(53, 70)

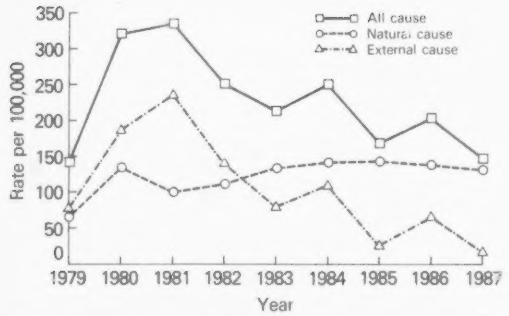

FIGURE 1—All Cause Mortality Rate of Male Inmates over Time, Natural Cause and External Cause Mortality Rates, Maryland State Prison System, 1979–87.

prisoners had lower all-cause mortality for the eight-year period (Table 1) and only suicide and infectious disease deaths were significantly elevated.

Discussion

We examined cause of death in long-term (prison) inmates. Although prisoners had lower all-cause mortality than the general population, significant elevations of suicide and infectious disease deaths were observed. Infectious disease mortality increased due to AIDS, which emerged in 1987 as the leading cause of inmate death. Although fewer than 20 AIDS cases were diagnosed before 1988, the problem will increase since 7 percent of entering male inmates were HIV infected,[18] and HIV transmission has been demonstrated.[19] AIDS prevention and treatment should remain a top correctional health priority. The need for suicide prevention was discussed elsewhere.[12]

Cancer mortality was 46 percent below the comparison population. Circulatory system deaths were also lower, in contrast to prior studies.[6]

External cause mortality overall was 26 percent below that of the general population. Homicide declined steadily and was 41 percent below that of the general Maryland population, although 13 percent of prisoners were convicted murderers. Improved security in the prison, including metal detector installation, is probably responsible for this decline. All injury deaths are potentially preventable and should be investigated.[10]

The epidemic of illicit drug overdose deaths between 1980 and 1982 is probably related to pentazocine (Talwin) use. Six of 16 overdose death certificates reported pentazocine. Pentazocine, although manufactured for oral use, was frequently injected by drug abusers. Its 1983 reformulation added the narcotic antagonist naloxone (inactive when taken orally), reducing overdose deaths nationwide[20,21] and in this prison.

There is a great deal of appropriate concern about poor conditions, riots, murders, outbreaks of illness, and standards of medical care in prisons. Nevertheless, the 39 percent lower Maryland prisoner mortality, similar to that reported in other studies,[5,6] suggests reason for optimism. Decreased mortality may be from a protected environment or lifestyle or a "healthy inmate effect" from selection factors.[5,6] Although data were unavailable from the medical parole program, in our experience premature discharges were rare (none for AIDS) and unlikely to explain lower mortality. Access to medical care may be better in prison than in the general population, which may lead to early detection and treatment of chronic disease. The effect of the availability of correctional officers trained in cardiopulmonary resuscitation needs further study. Limited access to weapons and motor vehicles is likely responsible for low injury mortality, although suicide is elevated. Data limitations preclude an analysis of the development of conditions over time.

The Supreme Court has reiterated the right of prisoners to adequate health care.[22] Any inmate death raises questions about cause, quality of care, and legal responsibility.[5,10] Despite our finding of lower mortality among prisoners, all prisoner death should be investigated to identify remediable health care or safety deficiencies. Improved prison health surveillance is needed for deaths and to determine the effect of prison health services on morbidity.

Long-Term Impact of Smoking Cessation on the Incidence of Coronary Heart Disease

ANNA N. A. TOSTESON, SCD, MILTON C. WEINSTEIN, PHD, LAWRENCE W. WILLIAMS, MS,
AND LEE GOLDMAN, MD, MPH

Abstract: Using a simulation model of the US male population, we estimated the long-term impact that future smoking cessation programs would have on the distribution and occurrence of coronary heart disease in males ages 35–84. For interventions that reduce the number of smokers by 25 percent in 1990, the number of men free of coronary heart disease is projected to increase by 416,787 (0.7 percent) in 2015, and the age-standardized absolute incidence to decline by 2.3 percent. Incidence rates and absolute incidences are projected to fall in men under age 65, but absolute incidence would rise in men over age 65, in large part because of the increased number of men who were at risk for coronary heart disease because of a reduction in non-coronary smoking-related mortality. These trends were more marked for greater smoking reductions and were generally unaffected in a variety of analyses using alternative assumptions, which considered smoking as a risk factor in the elderly, a lag-time before benefits from smoking cessation were realized and secular declines in smoking prevalence. Subject to the assumptions of our model, we conclude that smoking reductions will markedly reduce coronary heart disease, especially in younger age groups, and that this benefit will be slightly offset by a small increase in absolute incidence in elderly men. (*Am J Public Health* 1990; 80:1481–1486.)

Introduction

Smoking is a major risk factor not only for the development of coronary heart disease, but also for other diseases, such as lung cancer and chronic obstructive pulmonary disease.[1,2] Because these risks are to be reduced in persons who quit smoking,[3–6] a growing literature has investigated the effectiveness, economic consequences, and cost-effectiveness of smoking cessation techniques in clinical practice.[7–11]

However, the impact of smoking cessation programs on one outcome, such as coronary heart disease, may be confounded by its impact on the competing risks of developing other smoking-related diseases. We therefore sought to estimate the long-term effect that smoking intervention programs would have on the primary prevention of coronary heart disease in men who are initially free of heart disease at the time of the intervention. Our analysis focused on male smokers, because the risks of developing coronary heart disease as a function of smoking are more precisely measured for males than for females.[12]

Methods

The Coronary Heart Disease Policy Model, which has been described in full detail elsewhere,[13–15] is a state-transition computer-simulation model consisting of three integrated submodels: the Demographic-Epidemiologic Submodel, the Bridge Submodel, and the Disease History Submodel. The Bridge Submodel characterizes subjects for the first 30 days after they develop coronary heart disease, and the Disease History Submodel considers all events that occur among such persons after that 30-day period. Because our analysis focused on the effect of smoking-reduction programs on primary prevention of coronary heart disease, only the Demographic-Epidemiologic Submodel, which simulates the distribution of coronary heart disease risk factors in a population of 35–84 year old persons who are free of coronary heart disease, and computes the annual projected incidence of coronary heart disease on the basis of the simulated distribution, was used.

Each year, persons age 35 years who remain free of coronary heart disease enter the Demographic-Epidemiologic Submodel of the Coronary Heart Disease Policy Model, and persons who turn age 85 exit from the submodel. To exit from the submodel before age 85, persons must either die of non-coronary heart disease causes or develop coronary heart disease (at which time they enter the Bridge Submodel).

The risk factors used by the Demographic-Epidemiologic Submodel to assess each individual's risk of death and of developing coronary heart disease are age, sex, smoking status (no, yes; if yes, average number of cigarettes per day), diastolic blood pressure (≤94 mmHg, 95–104 mmHg, ≥105 mmHg), relative weight (≤109% of norm, 110–129% of norm, ≥130% of norm), and serum cholesterol (≤249 mg/dl, 250–299 mg/dl, ≥300 mg/dl). Based on the categories for each of these factors, the entire United States population that is free of coronary heart disease and is age 35–84 is divided into 5,400 cells, each with a specific value for each factor. For simplicity purposes, however, the model's outputs are collapsed into 10-year age ranges, thus yielding 540 strata.

Assumptions of the Model

The Demographic-Epidemiologic Submodel was initially constructed using the United States population for 1980 by age and sex[16] and the estimated proportion of persons with no history of coronary heart disease.[17] The distributions of smoking status, diastolic blood pressure, relative weight, and serum cholesterol were taken from the Second Health and Nutrition Examination Survey,[18] and the four risk-factor distributions were, for simplicity purposes, assumed to be independent, conditionally upon age range and sex. This assumption may either over- or underestimate the impact that risk factor changes would have on coronary heart disease. For example, a reduction in smoking could cause a decrease in blood pressure or an increase in weight, and an increase in weight could cause an increase in blood pressure.

The number of US residents who enter the model in each subsequent year after 1981 by turning 35 years of age was

Address reprint requests to Lee Goldman, MD, MPH, Division of Clinical Epidemiology, Department of Medicine, Brigham and Women's Hospital, 75 Francis Street, Boston, MA 02115. This paper, submitted to the Journal December 5, 1989, was revised and accepted for publication May 31, 1990.

estimated from projections of the US Bureau of the Census.[19,20] Risk factor changes with age were estimated from population based cross-sectional data.[18]

For each of the 540 cells, logistic regression coefficients for all-cause mortality and for developing coronary heart disease were based on data from the Framingham Heart Study.[12] The age- and sex-specific coefficients that were used for all risk factors in the Demographic-Epidemiologic submodel were obtained from the Framingham Heart Study's 30-year follow-up, and define the relative odds of death and heart disease for persons with the risk factor in comparison to a baseline group. These raw coefficients were smoothed by age for each sex by means of a weighted least squares regression of the Framingham coefficients on the mid-point of each 10-year age interval, where the weights used were the inverse of the coefficient's standard errors for coronary heart disease incidence. This method gave more weight to the more stable (i.e. smaller standard error) coefficients. The model's coefficients and standard errors that were obtained using this method are compared with the actual Framingham coefficients in Table 1. Note that for persons ≥65 years the smoothed coefficients were negative (−0.0023 for 65–74 years and −0.0136 for 75–84 years) and were therefore set to zero. This approach has been used by others,[8] and is reasonable because several studies indicate non-significant differences in risk of coronary heart disease between smokers and nonsmokers over age 65.[12,21] Overall mortality and coronary heart disease incidence rates were based on US Vital Statistics.[22] Incidence rates for ages 35–74 were assumed to follow those observed in the Framingham Heart Study,[23] with a secular adjustment for the decline in coronary heart disease incidence since the beginning of the Framingham Heart Study,[24] and with extrapolation to ages 75–84 and linear interpolation to smooth the age-specific annual rates.[13]

Intervention

Using the interactive intervention feature of the model, we studied the effect of interventions that produce a substantial reduction in the number of male smokers in the year 1990 by 25%, 50%, and 75%, respectively, on the United States population in the year 2015, 25 years after the reduction was achieved. Interventions were assumed to apply equally across all age groups. The measures that were used to assess the impact of the smoking interventions were the percent change over expected baseline values (i.e., where no smoking intervention is modeled) that the smoking reductions would have on the following measures in the year 2015: a) size of population free of coronary heart disease, b) coronary heart disease incidence rates and c) absolute incidence (the total number of new cases) of coronary heart disease.

TABLE 1—Smoking Coefficients and Standard Errors Used in Demographic-Epidemiologic Model for Determining Risk of Developing Coronary Heart Disease

Age (years)	Model*	Framingham
35–44	0.0316 (0.015)	0.029 (0.010)
45–54	0.0203 (0.010)	0.015 (0.005)
55–64	0.0090 (0.008)	0.016 (0.004)
65–74	0.0 (0.011)	0.002 (0.006)
75–84	0.0 (0.017)	−0.040 (0.023)

*Model coefficients obtained from smoothing Framingham logistic regression function coefficients (see text for details).

Sensitivity Analyses

The variations in our results that would be caused by changes in the coefficients of the logistic risk function for developing coronary heart disease were determined by repeating our analysis four times, using different sets of coefficients each time. The first sensitivity analysis used the actual Framingham coefficients and allowed us to assess the impact that the smoothed coefficients had on our results. The second and third sensitivity analyses used the smoothed coefficients, but first increased and then decreased them by one standard error. These analyses allowed us to assess the effect that interventions on smoking would have if smoking were of more or less importance as a risk factor for coronary heart disease than originally assumed. The fourth analysis examined the impact that a 50 percent smoking reduction would have when smoking was considered as a risk factor for the development of coronary heart disease in the elderly. In this analysis, the smoothed coefficient for persons ages 55–65, 0.009 (Table 1) was applied to persons ≥65.

We also evaluated the impact that delaying the benefits of intervention programs by three years would have on our results. For these analyses, cessation programs begun in 1990 were assumed to have no effect until 1993.

Finally, we evaluated the impact of new smoking interventions on coronary heart disease incidence under the assumption that secular changes in smoking prevalence are already occurring independently of any new intervention programs.[25] For these analyses we estimated the incidence rate and absolute incidence of coronary heart disease in 2015 that would occur if current secular declines continued at a linear rate as they have since 1974[25] through 2000. These estimates were used to compute the incremental change in coronary heart disease incidence that would occur in 2015 if in 1990 a new intervention to reduce smoking by 25, 50, or 75 percent was combined with the projected secular decline through the year 2000.

Results

Increase in Population at-Risk

The projected long-term effect of each smoking intervention within each age group was to increase the number of men at risk for coronary heart disease (i.e. men alive who are free of coronary heart disease) (Table 2). These increases occur in large part because fewer men would die of smoking-related non-coronary diseases if there were reductions in smoking. The increases range from 54,565 to 301,925 persons, 25 years after a 50 percent reduction in smoking prevalence is achieved. Men ages 65–74 in 2015, who were ages 40–49 at the time of the intervention in 1990, had the largest percent increase.

Standardized Absolute Incidence

After adjusting for population differences, the overall reduction in the number of incident coronary heart disease cases in the year 2015, which is 25 years after the smoking reductions are achieved, is projected to range from 2.3% to 5.9% (Table 3). For ages 65–74, there are estimated to be small increases in the number of cases of coronary heart disease under some levels of smoking reduction, and for persons ≥75 years the number of cases is unchanged.

Incidence Rate

The projected baseline rate of coronary heart disease incidence in the United States male population in the year 2015, assuming that cohort-specific risk factor distributions

35–84	(−2.3)	(−3.9)	(−5.9)

change with age as they have historically, resulted in coronary heart disease incidence rates between 0.29 and 1.96 per 100 (Table 4A). In the year 2015, 25 years after each level of smoking cessation is achieved, there were large decreases in the coronary heart disease incidence rates in the younger age groups. However, a 25 percent reduction in the number of smokers would have no influence on coronary heart disease incidence rates in males over age 65. Larger percent reductions in the number of male smokers would actually *increase* the coronary heart disease incidence rate among 65–74 year olds, while leaving coronary heart disease incidence among 75–84 year olds unchanged. The reasons for these increases are as follows: a) the pool of elderly survivors has been enriched with non-smokers who have slightly less favorable cholesterol levels, blood pressures, and weights; b) many of the at-risk smokers have already developed coronary heart disease; and c) Framingham data indicate that smoking is not a risk factor for coronary heart disease in the elderly (Table 1).

Absolute Incidence

The projected percent change over baseline estimates in the annual absolute incidence of new coronary heart disease cases (i.e. total number) 25 years after each level of smoking cessation is achieved is given in Table 4B. Smoking inter-

TABLE 4—Projected Percent Changes (in parentheses) over Baseline Values for CHD Incidence Rate, Absolute CHD Incidence, and Total CHD Prevalence, 25 Years after each level of Smoking Reduction is Achieved

A. Change in CHD Incidence Rate (per 100 among males free of CHD)

Age (years)	Baseline Incidence Rate	Change in Incidence Rate for Each Level of Smoking Reduction		
		25%	50%	75%
35–44	0.29	(−10)	(−17)	(−24)
45–54	0.64	(−5)	(−8)	(−13)
55–64	1.42	(−1)	(−3)	(−4)
65–74	1.81	(0)	(+1)	(+1)
75–84	1.96	(0)	(0)	(0)
35–54	0.47	(−6)	(−11)	(−16)
35–84	0.96	(−2)	(−4)	(−5)

B. Change in Absolute CHD Incidence (among males free of CHD)

Age (years)	Absolute Baseline Incidence	Change in Absolute Incidence for Each Level of Smoking Reduction		
		25%	50%	75%
35–44	50,471	(−9)	(−16)	(−22)
45–54	119,111	(−4)	(−8)	(−11)
55–64	219,786	(0)	(−1)	(−1)
65–74	149,072	(+1)	(+2)	(+4)
75–84	63,171	(+1)	(+2)	(+3)
35–54	169,582	(−5)	(−10)	(−15)
35–84	601,611	(−1)	(−2)	(−3)

*CHD: Coronary heart disease

ventions did not reduce absolute incidence of coronary heart disease as greatly as they reduced coronary heart disease incidence rates. In particular, the total number of new coronary heart disease cases *increases* for males over age 65. This is because absolute incidence reflects the size of the population at risk, which increases for all age groups as a result of smoking interventions.

Sensitivity Analyses

Changes in Smoking Coefficients—Changes in the smoking coefficients would alter estimates of coronary heart disease incidence rates and absolute incidence equally in younger men. However, under all of our sensitivity analyses (Table 5), the absolute incidence of coronary heart disease would increase in men over age 65. For example, if the actual raw, unadjusted Framingham logistic risk function coefficients were used rather than the smoothed coefficients, the results changed only to a minor degree. The largest difference was in men ages 75–84, in whom the Framingham coefficients are least stable. In this age group, the projected increase in the absolute incidence of coronary heart disease would be even more dramatic (4% higher) with the raw coefficients.

If smoking were not as strong a risk factor for coronary heart disease (i.e. if coefficients were decreased by one standard error), coronary heart disease incidence rates would still decrease for males under age 65, and the effects on absolute coronary heart disease incidence would be approximately one-half as large as under the baseline assumptions. In contrast, if smoking were a more powerful risk factor for coronary heart disease (i.e. if coefficients were increased by one standard error), a 50 percent reduction in the number of smokers in 1990 would result in reductions in coronary heart disease incidence rates by 2015 for *all* age groups. However, under both these scenarios the absolute incidence of coronary heart disease would increase in men over age 65.

When smoking was modeled as a risk factor for development of coronary heart disease in persons ≥65, incidence rates declined in the older age groups. However, absolute incidence still increased (by +1% rather than +2%) in persons ≥65.

Lag Time—Because smoking cessation programs may not produce immediate benefits, the analysis was repeated under the assumption that there is a three-year lag before benefits from smoking cessation would be realized. When the effects of smoking cessation programs begun in 1990 were delayed until 1993, the results changed by less than 1 percent.

Consideration of Future Secular Changes—When the analysis considered the current secular changes in smoking prevalence and assumed that rates of change would continue through the year 2000,[25] the incidence rates and absolute incidences in 2015 were different from those that would pertain if current secular trends do not continue. For example, a continuation of current secular rates of change would be about equivalent to a new intervention that yielded a 25 percent reduction in smoking in 1990.

When the secular decline through 2000 was used as the baseline for estimating the effects of new intervention programs to reduce smoking rates in 1990 by an additional 25, 50, or 75 percent, the effects of the new programs were dampened, but followed the same patterns previously reported. For example, the incremental impact of a 50 percent reduction in the number of smokers in 1990 when combined with a continuation in the secular decline through 2000 was less than the incremental impact of a 50 percent reduction in smoking rates if there are no secular declines, but greater than the incremental impact of a 25 percent reduction in smoking rates if there are no secular declines independent of

TABLE 5—Percent changes[*] over baseline values (i.e., no smoking intervention) for incidence rate and absolute incidence of CHD under alternate logistic risk function coefficients when a 50% decrease in smoking is achieved in 1990.

A. Change in Incidence Rate of CHD in 2015

	Coefficients Used in Logistic Risk Function				
Ages (years)	Smoothed Coefficients %	Unadjusted Coefficients %	Smoothed −1 S.E. %	Smoothed +1 S.E. %	Smoothed Elderly[†] %
35–44	−17	−17	−7	−28	−17
45–54	−8	−6	−5	−14	−8
55–64	−3	−5	−1	−5	−3
65–74	+1	0	0	−2	−2
75–84	0	+5	0	−1	−2

B. Change in Absolute Incidence of CHD in 2015

	Coefficients Used in Logistic Risk Function				
	Smoothed Coefficients %	Unadjusted Coefficients %	Smoothed −1 S.E. %	Smoothed +1 S.E. %	Smoothed Elderly[†] %
35–44	−16	−15	−8	−25	−16
45–54	−8	−5	−4	−12	−8
55–64	−1	−4	+1	−3	−1
65–74	+2	+2	+1	+2	+1
75–84	+2	+6	+1	+3	+1

[*] Note that changes are calculated relative to baseline simulations using the type of coefficients specified. For example, the −28% change in the incidence rate for 35–44 year olds that is observed when smoothed +1 S.E. coefficients are used, was calculated relative to baseline simulations that used the smoothed +1 S.E. coefficients. [†] Smoothed elderly refers to analyses done using smoothed coefficients (Table 1), with coefficients in persons ≥65 of 0.009 (the same coefficient as in the 55–64 age range).

new interventions for ages 35–64. For ages ≥65 years, the incremental impact of a 50 percent reduction when combined with a secular decline was identical to the impact of a 50 percent reduction when no secular declines were modeled.

Discussion

It is important to emphasize that because smoking is a risk factor for the development of many debilitating diseases, including chronic obstructive pulmonary disease and lung cancer, the ability of smoking cessation to improve the overall health of the population is clear. Our study is distinct from other studies, which have sought to measure the effects of risk factor interventions on coronary heart disease mortality and incidence,[3,5,6,21,26–28] because we have examined the long-term, steady-state, population wide impact that smoking cessation can have in the primary prevention of coronary heart disease among US males ages 35–84 who are free of coronary heart disease.

Our results indicate that interventions at a variety of levels would reduce the incidence rate of coronary heart disease for males under age 65, but that incidence rates would increase or remain unchanged for males ≥65 years of age. Note that although our baseline model, which was based on Framingham data, did not consider smoking to be a risk factor for the development of coronary heart disease among males ≥65 years,[12] males in this age group in 2015 were ages 40–59 at the time of the smoking intervention. Thus, they benefited from smoking reductions for at least six years before reaching age 65.

The fact that smoking interventions had the largest impact in reducing coronary heart disease incidence in the younger age groups is consistent with reports in the literature from several populations to indicate that smoking is a stronger relative risk factor for coronary heart disease in the young than in the elderly. The Framingham Heart Study reported incidence rates showing that non-smokers had a higher incidence of coronary heart disease than did smokers over the age of 65, however these differences were not statistically significant.[29] A study of British physicians by Doll and Peto[21] reported similar findings. Hennekens, *et al*,[30] noted that although the relative risks of coronary heart disease associated with smoking may decrease with age, the absolute risk increases. This phenomenon may be explained by the higher background risks of coronary heart disease that are associated with aging, and because many of the "at-risk" smokers may have already died from coronary heart disease or other smoking-related causes.[30,31]

A more recent analysis of data from the Framingham Heart Study indicated that smoking was of borderline significance as a risk factor for coronary heart disease in persons age 65 and older after adjusting for systolic blood pressure, left ventricular hypertrophy, total serum cholesterol, blood glucose, and Metropolitan relative weight.[31] A study of men under age 55 showed decreased risks of myocardial infarction after quitting smoking.[3] A similar phenomenon was reported for elderly men who quit smoking, but the endpoint was coronary heart disease mortality rather than myocardial infarction and this study included men with preexisting coronary heart disease.[5,6] On the basis of these reports and a prospective study that identified smoking as a risk factor for the development of new coronary heart disease in the elderly,[32] we undertook a sensitivity analysis, which modeled smoking as a risk factor in persons ≥65. Although decreases in incidence rates were observed for males ≥65, the intervention still impacted more substantially on the younger age groups.

One striking finding from our analysis is the small *increase* observed in the incidence of coronary heart disease among males ≥65 years of age that occurs under some of the smoking interventions, an effect that was observed even when smoking was modeled as a risk factor in the elderly. These increases emphasize that smoking interventions delay, but do not prevent, the development of coronary heart disease in the male population.

For all smoking interventions, decreases in absolute incidence were less pronounced than were decreases in the incidence rates for males <65 years, because of the larger population at-risk for coronary heart disease as a result of the decrease in smoking-related deaths under each intervention. In addition, there were increases in absolute incidence ranging from 1–4 percent for males ≥65 years under various scenarios. Thus, although decreases in the number of cases of new coronary heart disease would result from smoking interventions for younger persons, there would be a net increase in the number of incident cases of coronary heart disease for males ≥65 years of age.

On the basis of data from the literature, Goldman and Cook[33] estimated that the short-term reduction in coronary heart disease mortality due to an approximate 15 percent decrease in the number of smokers would be between 4.2 and 6 percent. Our results are somewhat different because they represent the differences observed in coronary heart disease incidence and absolute incidence in all men ages 35–84 free of heart disease 25 years after the smoking reduction was achieved. The overall standardized long-term impact of smoking interventions among males aged 35–84 was to reduce the total number of incident coronary heart disease cases by 2.3 percent when smoking rates were reduced 25 percent, by 3.9 percent when smoking rates were reduced by 50 percent, and by 5.9 percent when smoking rates were reduced by 75 percent. These reductions are less than might have been expected.

The Multiple Risk Factor Intervention Trial,[26] which studied men ages 35–57 over a six-year period, estimated that their observed 14 percent difference in smoking rates between the usual care and special intervention groups had the potential to produce a 5 percent difference in the number of coronary heart disease events. Our results for men ages 35–54 at 25 years after a 25 percent reduction in smoking rates was achieved indicate an age-standardized 6.6 percent difference in incident coronary heart disease cases. This estimate reflects the longer-term steady-state projected impact of smoking cessation on coronary heart disease incidence.

Our model depends in part on the accuracy of the National Vital Statistics data on which it is based. Although such data indicate a continued decline in ischemic heart disease (ICD Codes 410–414) mortality since 1980, a good portion of this decline is offset by increases in deaths due to diagnoses such as cardiac arrest and congestive heart failure.[22] These trends suggest that changes in coding practices since the institution of the revision of the ICD criteria in 1975[34] may have had an effect on the decline in deaths that are classified as due to ischemic heart disease.

In addition, the prevalence of ischemic heart disease, as estimated from the updates of the Health Interview Survey,[35] has increased by more than 10 percent since 1980. These trends, in the face of declining coronary risk factors, are consistent with more aggressive, early diagnosis of coronary disease rather than a true increase in atherogenesis. These issues indicate that the Coronary Heart Disease Policy Model will always be addressing a moving target, and thus we plan periodic updates as sufficient epidemiologic data on coronary disease incidence, prevalence, deaths and risk factor distribution become available, usually with a lag time of five or more years.

We did not explicitly consider the economic implications of smoking cessation. Oster, *et al*,[8] have predicted that the increased expenditures attributable to longer life-expectancy under smoking cessation programs are likely to be similar to the savings obtained from reductions in smoking-related illnesses, and Warner[7] has pointed out that the quality of life for non-smokers is likely to be higher than that of smokers. It is therefore not surprising that a variety of smoking interventions have been shown to be cost-effective.[11,36] Warner[7] also stated that although the incidence of cardiovascular disease would decrease in a smoke free society, the age-unadjusted incidence might increase. Our results provide further evidence in support of this conjecture. We conclude that although smoking interventions will not decrease the rate of coronary heart disease incidence for all age groups, the reduction in the number of cases of coronary heart disease among younger persons is substantial, and will offset the slight increases in the older age groups.

Overcoming Potential Pitfalls in the Use of Medicare Data for Epidemiologic Research

ELLIOTT S. FISHER, MD, MPH, JOHN A. BARON, MD, MSC, DAVID J. MALENKA, MD,
JANE BARRETT, MSC, AND THOMAS A. BUBOLZ, PHD

Abstract: We used Medicare data bases and US Census data to address two questions critical to the use of Medicare files for epidemiologic research. First, we examined the degree to which the population enrolled in the Medicare program is similar to the elderly resident population of the United States, as estimated by the US Census. We found small differences in the total population estimates but substantial differences by age and race. Second, we found that among Medicare enrollees, physician claims identify a small proportion of hip fracture cases which are not documented in the hospital discharge files. This proportion varies by age, region, and state within the United States. Calculation of rates based on Medicare hospital discharge data, and probably other hospital discharge data sets as well, must take these limitations into account. Use of all available Medicare data files can overcome these limitations. (*Am J Public Health* 1990; 80:1487–1490.)

Introduction

Administrative health care data bases, such as those maintained by the Health Care Financing Administration (HCFA) for the Medicare program, provide an increasingly accessible and widely used source of data for health care research. Medicare files have been used to study disease incidence and risk factors,[1–3] to document regional variations in treatment patterns,[4,5] to study hospital-associated mortality rates and quality of care,[6] and to evaluate the outcomes of specific surgical and medical treatments.[7,8]

Most concern about the validity of research findings based on the Medicare files has focused on issues related to the accuracy of diagnostic coding.[9–11] In this paper we highlight several other potential limitations of the Medicare data relevant to epidemiologic research by addressing two questions. First, can one assume that the population captured in Medicare files is the same as the elderly population of the United States? Second, do the Medicare hospital claims data identify all discharge records for Medicare enrollees who were hospitalized for a specific disease? The answers to these questions highlight how the careful use of Medicare data can overcome these limitations.

Methods

Population Estimates

We used US Census Bureau survey data and Medicare data files to estimate the age, sex, and race-specific counts of United States residents and Medicare enrollees who were over the age of 65 and were alive on July 1, 1985. Census estimates were taken from the Current Population Estimates.[12] Estimates for the Medicare eligible population were determined by using the 5 percent National HISKEW (live) file maintained by the Health Care Financing Administration. This file is a random sample of the Medicare population, based on the terminal two digits of the social security number and records the birth date, state of residence, race, gender, and Medicare eligibility status of beneficiaries who have been eligible for Medicare at some point and are not known to have died. (Deaths are recorded in a different file.) We excluded Medicare eligibles listed as residing outside the 50 States. We then determined age, sex, and race-specific counts of individuals in the HISKEW files generated on 12/31/84 and on 12/31/85. We averaged these counts and multiplied by 20 to estimate the Medicare population alive on July 1, 1985.

Hip Fracture Case Ascertainment

We searched the 5 percent National MEDPAR (hospital discharge) files for all discharges in calendar year 1985 with a discharge diagnosis of hip fracture (ICD-9-CM code 820.0–820.9) and the 5 percent Medicare Part B (physician and other provider) files for all claims specifically documenting the treatment of an acute hip fracture during calendar year 1985 (Current Procedure Terminology codes in the range 27230 to 27248). We developed a detailed algorithm to define acute hip fractures based on all claims submitted during the calendar year for potential cases, relying on both diagnosis and procedure codes and the dates of the related claims.[13] To be included, cases had to have at least one hospital claim specifying the diagnosis, or two Part B claims supporting the diagnosis of hip fracture. We excluded potential cases for whom the only evidence of treatment for the fracture was provided by a single Part B claim (3 percent of candidate cases). This decision was based on extensive review of all claims for a sample of these potential cases. Hip fracture cases were excluded if there was evidence that the treatment was provided for an earlier fracture or that the fracture resulted from metastatic cancer. We applied this algorithm to the data obtained from the 1985 5 percent national sample of Part A and Part B claims.

Results

Population Estimates

We compare the US Census estimate of the elderly population with our estimate of the Medicare population in Table 1. Overall, the Medicare population, as estimated from the HISKEW file, represents approximately 96 percent of the US Census estimate of the elderly population, but the proportion enrolled in Medicare varies sharply by both age and race. Among Whites, only 90 percent of the estimated elderly population between the ages of 65 and 69 is enrolled in Medicare and the proportion enrolled increases with age. Among Blacks, only 79 percent of the estimated population

Notes: Estimates of Medicare enrolled population calculated by taking average of live counts for 5% national sample for 12/31/84 and 12/31/85 in each relevant cell and multiplying by 20. Persons recorded as on the live HISKEW file but who were not residents of the 50 states were excluded. Census estimates were for 7/1/85, and were obtained from the Current Population Survey.[12]

HSK = Estimate of population from Medicare's HISKEW file.
CNS = Estimate of population from Current Population Survey.
H/C = Ratio of HISKEW estimate to CPS estimate.
C-H = Census estimate minus HISKEW estimate

aged 65 to 70 is enrolled in Medicare. Among Blacks, the proportion enrolled increases with age and exceeds the Census estimates among those over 80 years old. No notable differences between the two genders in the age-specific proportions enrolled in Medicare are apparent for Whites or Blacks. However, among those whose race is designated as "other," different patterns are apparent for males and females. Finally, for 3.1 percent of the individuals in the HISKEW file, race is designated as unknown, while the Census assigns a race designation to all individuals.

Case Ascertainment from Hospital Claims

Table 2 presents data on the proportion of hip fracture cases identified from the Part B (physician and other provider) files by state for 1985. Overall, 9.1 percent of hip fracture cases were identified from the Part B claims alone, and the proportion of cases so identified ranged from none in several states to a high of 32.8 percent in Virginia. The proportion of cases identified only through the Part B claims decreased significantly with age from 10.6 percent for those ages 65 to 69 to 8.4 percent for those age 85 and over (Chi square, 4df, 12.9, p = .01). However, no significant differences were found in the proportion of cases identified through the Part B files by gender or race.

Discussion

It is often assumed that the Medicare-eligible population corresponds closely to the elderly population of the United States and that studies of Medicare's hospital discharges will provide accurate estimates of hospital utilization among the elderly. One recent study has estimated hip fracture incidence rates using data from the US Census to estimate age/race/gender-specific denominators, while using Medicare hospital discharge data to calculate age, race, and gender-specific numerators for these rates.[3] Our data suggest that this approach must be taken with considerable caution.

We found that the Medicare population over the age of 65 differs in several important ways from the US Census estimates of the elderly population as a whole. The fact that only 95 to 96 percent of US elderly residents are enrolled in Medicare has been previously reported,[14] but breakdowns by age, gender, or race were not provided. Our data demonstrate that Medicare coverage varies substantially across these groups. Although some of the differences between Census and Medicare estimates of the population are trivial, others

are not. Consideration of sampling variations would further complicate interpretation of these differences. However, our analyses underline the obvious but important point that Medicare data provide information about the Medicare population; findings of studies that rely on Medicare data should be generalized to the elderly population as a whole with caution.

A full exploration of the causes of these differences is beyond the scope of this paper but would include issues related to criteria for Social Security eligibility, delayed enrollment for those still employed after age 65, and decisions by eligible persons about whether to enroll in either or both of the Medicare Part A and Part B programs. That the Current Population Estimates data from the US Census bureau are estimates subject to both sampling and measurement error may also play a role.

Equally important, coding conventions for race used by the Census and by Medicare differ. While the Census assigns a racial designation to all residents, approximately 3 percent of Medicare enrollees remain of unknown race. Given the White predominance in the elderly population and the possibility that substantial numbers of Whites are included in the group designated unknown, it would be inappropriate to group those of unknown race with either of the other two minority groups.

Finally, we must note that we cannot explain the relative excess of Medicare eligibles compared to Census estimates for the older age groups in several racial categories. Although Census undercounts in the oldest population are conceivable, this could also be explained by the failure to record a small number of deaths in the HISKEW file, a deficiency that would be magnified in the oldest age categories. We have found some indication that this might be the case. The 1985 5 percent national HISKEW file included 368 individuals over the age of 110, resulting in an estimated 7,360 individuals over this age in the population as a whole—an implausible figure. Nevertheless, given the close similarity of our overall estimates of the Medicare population based on HISKEW to HCFA's estimate of the proportion of the US population enrolled in Medicare (95 percent[14]), few deaths overall are apparently missed by these files and analytic difficulties caused by this problem would be serious only among the oldest old.

While it is obvious that outpatient claims would be required to analyze incidence rates for fractures that can be treated in an outpatient setting, we found that Medicare's hospital discharge files do not capture all treatment for hip fractures, a condition virtually always treated on an inpatient basis. Overall, physician claims were required to identify 9.1 percent of hip fracture cases; almost all of these physician claims were coded with the place of service "inpatient." For the majority of these cases, we found associated hospital claims with evidence of treatment for orthopedic conditions related to the hip, but no diagnosis of hip fracture. For the remainder, we must conclude that the hospital claims were either lost in the data transmission process or severely miscoded. It is reassuring that only small and insubstantial differences in fracture detection rates were found by age, race or gender, but the variation by state of residence might pose problems for analyses of geographic differences in incidence rates across states. We should also note that gaps in the physician claims are possible—Connecticut Part B claims were missing from the 1985 Medicare Part B 5 percent national file. A second caveat is that some Medicare enrollees may receive care in Veterans' Administration hospitals. We found that approximately 4 percent of New England hip fracture cases among males (and less than 1 percent among females) were documented in VA files.[13]

Our data illustrate two specific limitations beyond the accuracy of diagnostic coding that must be considered when using or reporting findings of studies that rely on Medicare data. First, the Medicare population cannot be assumed to correspond exactly with the resident US elderly population. Second, gaps in the Medicare hospital data must be acknowledged. These potential limitations could also apply to any analysis where different data sources are used for the numerator and denominator, or where hospital discharge data sets are not complete prior to release as public use tapes.

Most important, however, our data underline the feasibility of overcoming these limitations through the careful linkage of data from the multiple files available through the Medicare program. One of the cardinal rules in calculating rates is to ensure that the criteria used to determine eligibility for inclusion in the numerator should be as similar as possible to those used for assignment to the denominator. The Medicare enrollment file (HISKEW) can be used not only to define precisely denominators by age, race, sex, and mailing address (zip code), but can also be used to define identical inclusion criteria for both the numerator and denominator of rates. Finally, physician claims obtained from the Part B files and hospital claims from the Veterans' Administration can be merged with the Medicare hospital claims files to reduce the likelihood of missing cases in the study population of interest. When the limitations of administrative health care data bases are recognized and appropriate care exercised in their use, they can provide a valuable tool for epidemiologic research.

Prospective Payment and the Utilization of Physical Therapy Service in the Hospitalized Elderly

PETER HOLT, MD, AND CAROL HUTNER WINOGRAD, MD

Abstract: We studied the effect, in a university teaching hospital, of the prospective payment system (PPS) on utilization of physical therapy (PT), a non-reimbursable service; subjects were hospitalized patients aged 75 or older with non-PT-related diagnoses (myocardial infarction, pneumonia, congestive heart failure, and colectomy) and PT-related diagnoses (cerebrovascular accident and hip fracture). The proportion of patients referred for PT increased from 68 percent pre-PPS to 85 percent post-PPS for those with PT-related diagnoses and from 13 percent pre-PPS to 19 percent post-PPS for those with non-PT-related diagnoses. The mean number of sessions of PT decreased slightly for both groups: from 8.5 to 7.6 sessions for those with PT-related diagnoses and from 5.2 to 4.5 for those with non-PT-related diagnoses. In patients with PT-related diagnoses whose ambulatory status worsened during hospitalization, referrals for PT increased from 76 percent pre-PPS to 98 percent post-PPS. Referrals of comparable patients with non-PT-related diagnoses did not increase. Changes in provider education and efforts to reduce length of stay may account for these findings. (*Am J Public Health* 1990; 80:1491–1494.)

Introduction

In 1983, the Health Care Financing Administration (HCFA) introduced the prospective payment system (PPS). PPS created an incentive for hospitals to provide care at a cost at or below the established amount for a specific diagnosis-related group (DRG). Cost reduction could be accomplished by either reducing length of stay (LOS) or by decreasing utilization of ancillary services, such as physical therapy (PT). Nationally, LOS has decreased since the implementation of PPS.[1–5] In contrast, little attention has been directed toward the impact of PPS on utilization of PT.

This study focused on PT because it is a service used by hospitalized patients with a broad range of diagnoses. In 1986, approximately one in six hospitalized patients received some type of PT treatment.* Second, PT is a clinical service designed to improve mobility, ambulation, and independence. Because ambulatory status affects both quality of life and discharge status, the accessibility to and availability of PT is important, particularly to the frail elderly.[6–8]

Previous studies examining the effects of PPS on utilization of hospital PT services have shown mixed results. Several studies revealed a significant decrease in the mean number of PT sessions in hip fracture patients treated after the implementation of PPS.[2,5,9] These studies, however, did not evaluate the percentage of patients referred for PT. Another study found a significant increase in referrals for inpatient PT since 1983 in small acute care rural hospitals.[10] In contrast, a more recent study from 501 non-federal acute care hospitals reported a decrease in the number of patients referred for PT since 1983.[11] Neither of the latter two studies addressed which categories of patients (i.e. which DRGs) were more likely to have experienced changes in the pattern of utilization of PT.

The current study was designed to document the utilization patterns of PT services in the elderly prior to and after the implementation of PPS via two different indicators of PT utilization: percentage of referrals and mean number of sessions.

Methods

Medical records of patients 75 years of age or older discharged from Stanford University Medical Center (SUMC) were examined retrospectively for six consecutive years from September 1, 1980 through August 31, 1986. This represented four years prior to the implementation of PPS (9/1/80–8/31/84) and two years after the implementation of PPS (9/1/84–8/31/86).

Subjects

All patients discharged with one of the following six principal conditions were eligible: cerebrovascular accident (CVA); pneumonia; myocardial infarction (MI); congestive heart failure (CHF); hip fracture; and colectomy. These were further categorized into two groups: PT-related diagnoses which included CVA and hip fracture, and non-PT-related diagnoses which included pneumonia, MI, CHF, and colectomy. MI was not included in PT-related diagnoses because Medicare does not recognize it as a "rehabilitation diagnosis" in spite of the proliferation of cardiac rehabilitation programs.

After PPS was implemented, there was an incentive for chart abstractors in the Medical Records Department to be as specific as possible when coding. In the two years post-PPS, fewer patients than pre-PPS were discharged with CVA. Instead they were categorized with the specific etiology of CVA (e.g. embolic, thrombotic, or hemorrhagic) which resulted in a different ICD code. All other categories remained the same pre- and post-PPS.

The study sample (n = 917) was selected from a list of patients by use of tables of random permutations.[12] Because of the small numbers in the CVA category for the post-PPS years, all eligible patients were included.

Data Collection and Analysis

Data were abstracted from the medical records with the number of PT sessions counted only if the patient actually received therapy. The initial PT evaluation was counted as one session. The percentage of referrals and the mean number of sessions were calculated.

*Terbush TW: Estimates of physical therapy costs and usage by Medicare patients in FY 1986. Prepared for the American Physical Therapy Association, January 1987.

Ambulatory status was categorized as follows: unable to walk, walks only with the physical assistance of another person, ambulates independently with or without ambulation aids, or not obtainable. It was determined just prior to the admission illness or injury (i.e. pre-morbid ambulatory status) and at discharge. For those patients in whom ambulatory status was obtainable at both times, the difference between pre-morbid ambulatory status and discharge ambulatory status was scored better, worse, or the same.

Residence at admission and discharge was categorized as follows: independent home setting, board and care home, acute care facility, intermediate care facility (ICF), skilled nursing facility (SNF), or other type of facility. Any change in type of residence was recorded.

The predictor variable was relationship to PPS, divided into pre-PPS and post-PPS. The outcome variables were utilization of PT (measured by mean number of PT sessions and percent of patients referred to PT), length of stay, change in ambulatory status, and change in type of residence.

Results were analyzed using t-tests for the continuous outcome variables and chi-square tests for dichotomous outcome variables. Ninety-five percent confidence intervals were calculated for all results.[13]

Results

We identified 917 patient charts for review after random selection. Of these, 907 (99%) were available for review, 468 (98%) of the 475 cases in the pre-PPS and 439 (99%) of the 442 cases in the post-PPS period. The two groups were similar in terms of age, sex, marital status, type of residence, and in-hospital mortality (Table 1). Length of stay decreased by 1.6 days.

The proportion of patients referred for PT increased from 68 percent pre-PPS to 85 percent post-PPS (diff = 17%, CI = 7.4, 26.6%) for the PT-related diagnoses group and from 13 percent pre-PPS to 19 percent post-PPS (diff = 6%, CI = 0.3, 11.7%) for the non-PT-related diagnoses group. However, the mean number of PT sessions decreased slightly from 8.5 sessions pre-PPS to 7.6 sessions post-PPS (diff = 0.9, CI = −0.8, 2.6%) for the PT-related diagnoses group and from 5.2 sessions pre-PPS to 4.5 sessions post-PPS (diff = 0.7, CI = −0.7, 1.4%) sessions post-PPS for the non-PT-related diagnoses group (Table 2).

Patients with PT-related diagnoses whose ambulatory status worsened were referred for PT more often post-PPS (76% pre-PPS to 98% post-PPS, diff = 22%, CI = 9.5, 34.5%), while PT referrals of comparable patients with non-PT-related diagnoses showed no change. Discharge to a more dependent level of care increased for patients with PT-related diagnoses (44% pre-PPS to 59% post-PPS, diff = 15%, CI = 2, 28%), while no difference existed in the group with non-PT-related diagnoses.

TABLE 1—Demographic Data of Subjects Pre- and Post-Prospective Payment System

Item	Pre-PPS (N = 468)	Post-PPS (N = 439)	Difference (95% CI)
Age (Mean)	82.5	83.0	0.5 (−0.2, +1.2)
Sex (% Male)	38.0	38.0	0
Marital Status (% Married)	38.0	38.0	0
Residence (% Home)	86.0	84.0	2 (−13, +17)
Mortality (%)	16.0	13.0	3 (−11, +17)
Length of Stay (Number of Days)	10.7	9.1	1.6 (+0.7, +2.5)

The proportion of patients ambulating independently prior to admission did not change for the group with PT-related diagnoses however, there was a small decrease at discharge (54% pre-PPS to 46% post-PPS, diff = −8%, CI = −5, 21%). The proportion of patients in the non-PT-related diagnoses group that ambulated independently decreased prior to admission (95% pre-PPS to 90% post-PPS, diff = −5%, CI = 0.2, 9.8%) and at discharge (87% pre-PPS to 80% post-PPS, diff = −7%, CI = 0.03, 13.7%) (Table 3).

Discussion

This study documents an increase in the percentage of patients referred for PT after the implementation of PPS in a university hospital. This is a surprising and encouraging finding, because prior to the study we expected to find a decrease in utilization of PT services. Our findings do not substantiate previous concerns that the elderly would inevitably suffer from poorer quality of care under PPS, as hospitals under pressure to maintain their "bottom line" would reduce the provision of potentially beneficial services.

A small decrease occurred in the mean number of PT sessions administered in the post-PPS time period. This decrease was less than one might have expected given the considerable decrease in the LOS; this contrasts with the results of other investigators who found decreases in the LOS and mean number of PT sessions to be more closely related.[2,5,9]

Physicians, who must initiate the referral for PT, may have become more aware of the benefits of early mobilization and ambulation during acute illness; referral for PT services may help maintain mobility and thereby enable patients to be discharged sooner.

The overall ambulatory status of patients appears to have declined during the period of implementation of PPS. After PPS, patients with non-PT-related diagnoses (e.g. CHF and colectomy) were more dependent in ambulation both prior to admission and at discharge. These patients were admitted with medical and surgical conditions that in themselves did not directly affect neurological or musculoskeletal function and should not have had an impact on ambulation. This dependency in ambulation may reflect the findings of other investigators that the case mix of patients after PPS changed.[14] Acute care hospitals now provide care to more severely ill patients in need of the greatest intensity of service. For example, after PPS, patients with mild forms of pneumonia and CHF may have been treated as outpatients, while only the most debilitated patients were admitted to the hospital.

Since one of the primary indications for and goals of PT is to maintain ambulation, we also examined the change in ambulatory status of patients admitted before and after PPS, and the referral patterns for PT in these patients. Although no difference occurred in the percentage of patients whose ambulatory status worsened during the hospitalization before or after PPS, subgroup analysis revealed striking differences between PT-related and non-PT-related groups in referral for PT. Patients with strokes and hip fracture whose ambulation worsened were more frequently referred for PT after PPS. In contrast, comparable patients with medical and surgical diagnoses experienced no increase in referrals for PT after PPS.

TABLE 2—Utilization of Physical Therapy Services Pre- and Post-Prospective Payment System by Diagnostic Group

	PT-Related Diagnoses			Non-PT-Related Diagnoses		
	Pre-PPS	Post-PPS	Difference (95% CI)	Pre-PPS	Post-PPS	Difference (95% CI)
Percent Referred	68	85	+17 (+7.4, +26.6)	13	19	+6 (+0.3, 11.7)
Mean Number of PT Sessions	8.5	7.6	−0.9 (−0.8, +2.6)	5.2	4.5	−0.7 (−0.7, +1.4)

TABLE 3—Percent of Patients Ambulating Independently Pre- and Post-Prospective Payment System by Diagnostic Group

	PT-Related Diagnoses			Non-PT-Related Diagnoses		
	Pre-PPS	Post-PPS	Difference (95% CI)	Pre-PPS	Post-PPS	Difference (95% CI)
Pre-Morbid (Prior to Illness Causing Hospitalization)	90	90	0	95	90	−5 (+0.2, +9.8)
At Discharge	54	46	−8 (−5, +21)	87	80	−7 (+.03, +13.7)
Pre-Post Difference	−36	−44	+8 (−5, +21)	−8	−10	+2 (+3, +7)

Impaired mobility is a common problem in the elderly[15] that is frequently exacerbated by acute care hospitalization.** Simple bedrest, a common order on admission for acutely ill patients, can be devastating in the frail elderly.[16–18]

We reviewed a random selection of 12 patient charts from the non-PT-related group with a decline in ambulatory status, but were not referred for PT services. No consistent factor (e.g. patient refusal, severity of illness, physician preference) could be identified to explain the absence of a PT request. Referrals may be based on different standards of practice among groups of physicians. Neurologists and orthopedists may be more familiar with rehabilitation than are internists. One would hope that patients with impaired mobility regardless of their diagnosis would receive the necessary PT services prior to discharge.

An encouraging finding in our study was that the percentage of patients with non-PT-related diagnoses requiring placement in a more dependent level of care did not increase after PPS. This is corroborated by other investigators.[19,20] However, more patients in the PT-related group (e.g. hip fractures) required a more dependent placement after PPS. Several studies have reported similar findings;[2,5,9] change in case mix, as well as a decreased LOS may explain them. After PPS, patients with hip fractures and strokes may not have had adequate recovery time in the hospital to ambulate well enough to go back to their original type of residence.

We do not think the decrease in the number of patients with CVA diagnostic code, after the implementation of PPS, affected the comparability of the two groups because the change in coding specified only the type of stroke and not the location or associated functional disability. Both groups most likely had an equal need for utilization of PT services.

In 1984, the Palo Alto Veterans Administration Medical Center, a major teaching hospital for Stanford University Medical Center housestaff, established a geriatrics program with a strong rehabilitation focus for acutely ill, hospitalized elderly veterans. Many members of the housestaff rotated on this service to learn the principles of geriatric medicine. These concepts may have been integrated into their treatment plans when the housestaff returned to Stanford Medical Center for subsequent rotations. This may have affected PT referrals.

A home health care program was introduced at Stanford during the study period. Greater availability of in-house support services, including health aides, nurses, and rehabilitation therapists, may have had an impact on discharge planning and discharge location.

In summary, this study describes a changing pattern of utilization of PT since the implementation of PPS in a university hospital. Specifically, the percent of patients referred for PT increased. In spite of this finding, this study also suggests that patients with medical and surgical diagnoses who have impaired ambulation may not be referred for potentially beneficial PT services.

Conference Proceedings Available on Primary Care Research

As part of its emphasis on primary care for patients of all ages and conditions, the Agency for Health Care Policy and Research (AHCPR), in cooperation with several other agencies, convened a conference entitled "Primary Care Research: An Agenda for the 90s" in March 1990 at Colorado Springs, CO.

The conference explored many of the emerging issues expected to set the pace for primary care research during the 1990s, including: changing provider behavior, research with disadvantaged populations, medical treatment effectiveness in primary care mental health, community-oriented primary care, prevention research, outcome measurement issues, rural health, AIDS, substance abuse, practice-based research networks, and the federal perspective on primary care research.

These and other topics are presented in feature articles and commentaries in a new 147-page report resulting from the conference.

Single copies of the proceedings, *Primary Care Research: An Agenda for the 90s* (DHHS Pub. No. PHS 90-3460) are available from: AHCPR, Publications and Information Branch, 18–12 Parklawn Bldg., Rockville, MD 20857; (301) 443-4100.

Prevalence of Chronic Bronchitis among US Hispanics from the Hispanic Health and Nutrition Examination Survey, 1982–84

KI MOON BANG, PHD, MPH, PETER J. GERGEN, MD, MPH, AND MARGARET CARROLL, MSPH

Abstract: In the Hispanic Health and Nutrition Examination Survey (HHANES), Puerto Ricans had a higher age-adjusted prevalence of self-reported chronic bronchitis (2.9 percent, 95% CI = 2.2, 3.6) than Mexican Americans (1.7 percent, 95% CI = 1.3, 2.1) or Cubans (1.7 percent, 95% CI = 0.9, 2.5). The prevalence of chronic bronchitis was at least 2 times higher in smokers as compared to nonsmokers among Puerto Ricans and Cubans, but not for Mexican Americans. (*Am J Public Health* 1990; 80:1495–1497.)

Introduction

Chronic bronchitis is part of chronic obstructive pulmonary disease (COPD), the fifth leading cause of mortality in the US. Mortality from COPD increased 43 percent between 1979 to 1986 (22.2/100,000 to 31.8/100,000).[1] The epidemiology of chronic bronchitis has been described in numerous studies of US Whites.[2–4] Little is known about the prevalence of chronic bronchitis among the US Hispanic population.

We present estimates of the prevalence of self-reported chronic bronchitis among the three Hispanic subgroups and the association between chronic bronchitis and measured risk factors among Hispanics based on the 1982-84 Hispanic Health and Nutrition Examination Survey (HHANES).

Methods

The HHANES was conducted by the National Center for Health Statistics from 1982 to 1984. The target population consisted of individuals ages 6 months–74 years in the three major Hispanic subgroups in selected areas of the United States: Mexican Americans in five Southwestern states (Arizona, California, Colorado, New Mexico, and Texas); Cubans in Dade County, Florida; and Puerto Ricans in the New York City area. The sample design of HHANES was a multistage, stratified, clustered sample of each of the Hispanic subgroups. Details of the HHANES have been published.[5]

In the household interview, respondents were asked two questions about chronic bronchitis: 1) "Has a doctor ever told you that you had chronic bronchitis?", 2) "Do you still have chronic bronchitis?" Positive responses to both questions were used to define chronic bronchitis.

All statistical analyses were carried out using programs compatible with the Statistical Analysis System.[6] Since HHANES was based on a complex survey design, sampling weights were used to estimate the prevalence of chronic bronchitis and complex samples variances were estimated by multiplying the simple random sample variance estimates by an average design effect.[7,8] To compare the prevalence of chronic bronchitis among the three Hispanic subgroups, estimates of chronic bronchitis were age-standardized to the distribution of the 1980 population. The trend for the age-specific prevalence was analyzed using the Armitage method.[9] The logistic regression analyses were performed using RTILOGIT program.[10] Odds ratios (ORs) and 95% confidence intervals (CI) of ORs are presented.[11]

Results

The response rates were 79.2 percent for Mexican Americans, 73.9 percent for Cuban Americans, and 80.3 percent for Puerto Ricans (Table 1). The level of nonresponse did not vary across age, race, sex, or income groups. The age distributions of the analytical sample were similar in the Mexican American and Puerto Rican samples, but the Cuban American sample was considerably older. The proportion of heavy smokers (> 20 cigarettes/day) among Puerto Rican and Cuban smokers was much higher than among Mexican American smokers (Table 1).

The age-adjusted prevalence of self-reported chronic bronchitis was 1.7 percent (95% CI: 1.3, 2.1) for Mexican Americans; 1.7 percent (95% CI: 0.9, 2.5) for Cuban Americans; and 2.9 percent (95% CI: 2.2, 3.6) for Puerto Ricans (Table 2); prevalence increased slightly with age in both males and females among Mexican Americans ($p < 0.001$). Failure to find a clear increase in prevalence with age among Cuban Americans and Puerto Ricans may be due to the smaller sample size of these groups.

To assess the role of measured risk factors of self-reported chronic bronchitis, logistic models were fitted using age, sex, smoking, and poverty status (Table 3). Former smokers were excluded from the analysis because of small numbers. In the model for Puerto Ricans, age (OR = 1.03, 95% CI = 1.01, 1.05), sex (OR = 2.69, 95% CI = 1.38, 5.26), and cigarette smoking (OR = 2.72, 95% CI = 1.57, 4.71) were significant risk factors for chronic bronchitis. However, only smoking (OR = 2.75, 95% CI = 1.14, 6.62) for Cuban Americans and age (OR = 1.03, 95% CI = 1.01, 1.05) for Mexican Americans were significantly associated with chronic bronchitis.

CI: Confidence interval.
*No reported chronic bronchitis.
**Age-adjusted prevalence.

Discussion

The high age-adjusted prevalence of chronic bronchitis among Puerto Ricans may have been due to the higher proportion of heavy cigarette smokers among Puerto Ricans and/or the high exposure to air pollution in New York City. Females had consistently higher age-adjusted prevalences of chronic bronchitis than males: in Puerto Ricans, 3.8 percent for males, 1.6 percent for females; in Mexican Americans, 1.8 percent for females, 1.6 percent for males; in Cuban Americans, 1.9 percent for females, 1.4 percent for males. A recent study on 2,111 Hispanics in New Mexico reported that the prevalence of chronic bronchitis among females was 4.3 percent as compared to 2.9 percent for males.[12] In the 1978 National Health Interview Survey, the prevalence of chronic bronchitis was higher in females (3.7 percent) than in males (2.9 percent).[13] A possible explanation for the female predominance might be that females visit clinics more often and are therefore aware of this diagnosis.[14] In contrast, some studies reported that the risk of chronic bronchitis was more than three-fold greater for men than women.[15]

The failure to find an association between smoking and chronic bronchitis in Mexican Americans may be due to the high proportion of light smokers. Other studies have shown cigarette smoking to be one of the most important risk factors for chronic bronchitis.[16,17] A recent study[18] found that heavy smokers had a six-fold increase in chronic bronchitis as

TABLE 3—Estimates of Odds Ratios with 95% Confidence Intervals of Risk Factors for Chronic Bronchitis[a]

	Odds Ratio	95% Confidence Interval
Mexican Americans		
Sex	1.09	0.66, 1.82
Age	1.03	1.01, 1.05

Sex (1 = female, 0 = male), Age (continuous)
Smoking (1 = smokers, 0 = nonsmokers), Poverty (1 = below, 0 = at/above)
a) Past smokers excluded.

compared to nonsmokers. Other important risk factors of chronic bronchitis, not measured in HHANES, include occupational exposures,[19-21] airborne irritant gases,[22,23] viral or bacterial infection,[4,24] and familial aggregation.[25]

The American Thoracic Society's definition of chronic bronchitis requires a history of three months of cough and phlegm or sputum for more than two consecutive years.[26] This information was not collected during HHANES. The use of diagnosed cases only will underestimate the prevalence of chronic bronchitis. Other potential biases which may occur cannot be estimated in the data set but must be kept in mind when interpreting the results of this study.

In conclusion, our results show that chronic bronchitis was more prevalent in Puerto Ricans than Cuban Americans or Mexican Americans. Cigarette smoking was an important risk factor for chronic bronchitis among Puerto Ricans and Cuban Americans. Thus, smoking prevention and smoking cessation programs in the Hispanic population would help reduce the risk of chronic bronchitis.

Prevalence and Restrictiveness of Smoking Policies in King County, Washington, Manufacturing Worksites

SUSAN KINNE, PHD

Abstract: This study examined prevalence of smoking policies and of significant smoking restrictions in a 1988 random sample of 1,528 manufacturing companies in the Seattle, Washington area, and related these characteristics to worksite size and industry type. Sixty-nine percent of companies had formal smoking policies and 85 percent regulated smoking to some degree. Workforce size was directly related to prevalence of significant smoking restrictions, but when type of industry was controlled, the linear trend in the size/prevalence relationship was sustained in only three of the 18 industry groupings. (*Am J Public Health* 1990; 80:1498–1500.)

Introduction

Policies regulating workplace smoking have been imposed to reduce fire hazard, protect equipment[1] and, most recently, to protect nonsmokers from exposure to environmental tobacco smoke.[2] Efforts to assess the effects of these policies on smoking reduction and cessation have been reported.[3–8] Little is known about policy prevalence and content, because most policy surveys have had nonrandom sampling techniques, undefined populations, and low response rates that limit the quality of the data.[9–11] Few studies have clearly distinguished among types of policies or investigated relationships between organizational characteristics and policy content.[12] This research was designed to provide an accurate assessment of the prevalence of degrees of policy restriction on smoking in a geographically defined population of organizations employing many smokers, and to describe the relationship between policy, organizational size, and industry type.

Methods

These data are from a random sample of all King County (Washington) manufacturing worksites, surveyed by telephone between November 1988 and July 1989. King County includes the city of Seattle. The sampling frame, the set of all companies with manufacturing Standard Industrial Codes (SIC),[13] and King County zip code mailing addresses, was identified by a commercial broker (n = 2,883). Two-thirds of these companies (n = 1,922) were randomly selected for the study. Three hundred ninety-four companies were deleted as ineligible (disconnected numbers; non-County or non-manufacturing concerns; and one-person companies) on grounds that such companies would not use policy to control behavior. The response rate among eligible companies was 91.3 percent (1,395/1,528).

Companies in the sample received a letter describing the study, followed by a 10-minute telephone interview with the company head or a person identified by the head as knowledgeable about smoking policy. The informant was asked, "Does your organization presently have a policy on where employees can and cannot smoke in your buildings and facilities?" Policy was defined as a directive on smoking by the company head or governing body, communicated to employees in written or unwritten form.

Policies vary in the degree to which they limit smoking. Table 1 gives the policy response categories in order of increasing restrictiveness. Worksites also can be grouped by their degree of policy-mandated protection against environmental tobacco smoke (ETS) and the inferred company attitude toward smoking. Companies with no policy, with non-restrictive policies, or with smoking allowed except in no-smoking areas offer little ETS protection and accept smoking as the norm.[14] These were labeled "Smoking Allowed." Companies in which nonsmoking is the norm[14] were grouped as "Significant Restrictions." These include worksites that limit smoking to designated smoking areas and those that ban smoking completely, thereby limiting ETS exposure substantially. The prevalence of "Significant Restrictions" was examined for worksites of differing workforce size and industry type.

TABLE 1—Distribution of Smoking Policy Restrictions by Number of Employees in King County (WA) Manufacturing Worksites

Policy Restrictiveness	Number of employees 2–10	11–25	26–100	>100	Total %/n
(n of companies in category)	(700)	(326)	(269)	(100)	(1395)
Smoking allowed					
No policy on smoking	19.7%	15.6	4.5	1.0	14.5/202
Policy allows smoking everywhere	0.0	0.6	0.4	1.0	0.3/4
Non-policy smoking restrictions	19.6	14.7	11.9	10.0	16.3/227
Smoking except in no-smoking areas	4.9	9.2	14.1	10.0	8.0/112
(subtotal: smoking allowed)	(44.1)	(40.2)	(30.9)	(22.0)	(39.1/545)
Significant restrictions					
Smoking only in designated areas	12.9	26.7	40.1	57.0	24.5/342
No smoking allowed	27.9	27.0	23.4	16.0	25.9/362
No smoking, prefer to hire nonsmokers	10.9	4.9	4.5	4.0	7.7/108
No smoking, only hire nonsmokers	4.3	1.2	1.1	1.0	2.7/38
(subtotal: significant restrictions)	(55.9)	(59.8)	(69.1)	(78.0)	(60.9/850)

Total companies	1,395					60.9%		

Results

We found that 69.2 percent (966/1,395) of companies reported having a policy on where employees could smoke in buildings and facilities (Table 1). Four of these companies (0.3 percent) stated that they had adopted a smoking policy that explicitly permitted smoking in all parts of the worksite, leaving 68.9 percent (962/1,395) of companies with policies that restricted smoking. An additional 227 companies without smoking policies reported that smoking was not allowed in parts of their worksite. When the latter two categories were combined, the data show that smoking was limited to some degree in 85.2 percent (1,189/1,395) of responding worksites. Companies that banned smoking completely, with or without hiring policies on smokers, comprised 36.3 percent (508/1,395) of worksites surveyed. The prevalence of significant restrictions on smoking was 60.9 percent (850/1,395).

The number of full-time employees, a measure of company size, was related to smoking policy (Table 1). Having a formal smoking policy increased with workforce size, as did prevalence of significant smoking restrictions, although the likelihood of a total smoking ban was greatest in the smallest companies. Companies without smoking restrictions were in the minority in every size category.

This relationship between workforce size and prevalence of significant restrictions varied by type of manufacturing activity. When SIC grouping was controlled, the chi-squared test for trend for the relationship between size and prevalence was significant for only three of the 18 SIC groups (Table 2). Five groups showed weak size/prevalence relationships ($.05 < p < .10$), not all of which can be attributed to small numbers of cases. In the remaining 10 groups, the size/prevalence relationships were erratic, suggesting that factors peculiar to those industries may account in part for the distribution of significant smoking restrictions.

Discussion

The results of this survey demonstrate general acceptance of the concept of worksite smoking control among King County manufacturers of all sizes. The majority of employees in these industries now enjoy some protection from exposure to environmental tobacco smoke.

These data share some of the limitations of previous work on smoking policy. We have no measures of reliability or validity of the questions used to inquire about policy, and respondents' meaning of "a policy on smoking" may vary.[12] Although the survey data estimate the extent of policies, they provide no information on policy enforcement, making it impossible to estimate actual impact on air quality. Lastly, these data reflect practices of manufacturers in one geographic area, and may not be representative of this sector's smoking policies in other parts of the country. A number of prominent employers and local governmental units have "gone smoke-free" in King County in the past few years. Washington State, King County, and the City of Seattle impose relatively stringent restrictions on public smoking. None of these jurisdictions requires that private employers or worksite environments have policies (although such a law, exempting small worksites, has been proposed by the State Legislature), but public acceptance of smoking restriction is widespread. This attitude may explain the survey's finding that extensive control of smoking in the worksite may be accomplished without legislative mandate.

ACKNOWLEDGMENTS

This research was supported by the National Cancer Institute, CA-34847. The advice of Dr. James E. Grizzle much improved the data analysis. A portion of the data were presented at the 118th Annual Meeting of the American Public Health Association, New York, New York, Sept. 30–Oct. 4, 1990.

Depressive Symptoms and Cigarette Smoking among Latinos in San Francisco

Eliseo J. Pérez-Stable, MD, Gerardo Marín, PhD, Barbara V. Marín, PhD, and Mitchell H. Katz, MD

Abstract: We administered the Center for Epidemiological Studies Depression (CES-D) Scale to 547 San Francisco Latinos as part of a random digit dialing telephone survey to evaluate smoking behavior. Both men and women current smokers had the highest mean CES-D levels (9.7 and 14.3, respectively). Logistic regression analysis adjusting for gender, acculturation, education, age, and employment showed that current smokers had an odds ratio of 1.7 (95% CI = 1.3, 2.2) for significant depressive symptoms compared to former smokers (OR = 1.1; 95% CI = .8, 1.6) and never smokers (OR = 1). (*Am J Public Health* 1990; 80:1500–1502.)

Introduction

Cigarette smoking continues to be the most common cause of preventable morbidity and mortality in the US.[1] Three community studies[2–4] and a study of adolescents[5] have reported on possible relations between smoking status and depressive symptoms with conflicting results.

Five population-based surveys of Latino communities in California have reported a high rate of depressive symptoms compared to non-Latino White samples.[6–11] Female gender,[6,8,9] younger age,[6,9] formerly married status,[9–11] lower income,[6,10,11] less education,[9,10] unemployment,[11] and inability to speak English[9] have been associated with a higher level of depressive symptoms. Factors associated with increased depressive symptoms in the Hispanic Health and Nutrition Examination Survey were female gender, low educational achievement, low income, and US birth combined with Anglo-oriented acculturation.[12] To date, no study has examined smoking status as it relates to depressive symptoms among Latinos.

Although the overall prevalence of cigarette smoking among US Latinos is somewhat lower than that for Whites or Blacks, this rate reflects the substantially lower smoking proportions of Latino women compared to men.[13–15] Increasing acculturation to the mainstream US culture results in more smoking by Latino women, but less among Latino men, and thus may eventually narrow this smoking gender gap.[15]

We examined the possible relation of depressive symptoms, cigarette smoking status, and demographic variables, within a community survey of Latinos in San Francisco, part of an ongoing evaluation of a community intervention to promote smoking cessation.

Methods

Subjects were sampled from the 27 census tracts in San Francisco with at least 10 percent Latinos and representing two-thirds (N = 55,541) of all Latinos (N = 83,373) living in San Francisco according to the 1980 US Census.[16] Telephone prefixes corresponding to the census tracts were identified using a reverse telephone directory and the Mitofsky-Waksberg[17] method for random digit dialing was applied.[18] This method identifies nonworking and other ineligible prefixes in a first stage.

A household was eligible if, on the initial question, the person answering the telephone self-identified as Latino or if the majority of residents were Latino. Within a given household, the Latino adult between 18 and 65 years of age who had most recently celebrated a birthday was invited to respond. A structured questionnaire was administered anonymously by trained bilingual interviewers after subjects gave verbal consent. Participants responded in Spanish (69.7 percent) or in English (30.3 percent); 5.5 percent of eligible participants refused to be interviewed.

Depressive symptoms were measured using the Center for Epidemiological Studies Depression scale (CES-D)[19] which has been applied in Spanish in other studies with Latinos.[6–8,11] A CES-D score of 16 or more is considered to represent significant depressive symptoms, and validation studies with psychiatric and community samples showed that approximately one-third of persons scoring 16 or more on the CES-D are diagnosed with clinical depression.[20,21]

Never smokers were defined as persons who had smoked less than 100 cigarettes in their entire life. Gender, age,

Marín and Dr. Katz are with that same department; Dr. G. Marín is with the Department of Psychology, University of San Francisco. This paper, submitted to the Journal August 18, 1989, was revised and accepted for publication April 9, 1990.

education, employment in last two weeks, birthplace, and national background were asked, but marital status was not determined. A five-item acculturation scale with excellent reliability and validity was administered and scores were dichotomized into low (1 to <3) and high (≥ 3 to 5) acculturation groups.[22]

Data were analyzed using a standard statistical software package for a microcomputer (BMDP).[23] Variables that have been shown in previous research to be associated with depression were entered into a logistic regression model along with smoking status: acculturation (low/high), age (<30 / ≥ 30 years), employment status (yes/no), and education (<12 years / ≥ 12 years). The categorical variable smoking status was coded into two variables: current smoking (yes/no) and former smoking (yes/no).

Results

A total of 604 Latinos agreed to be interviewed by telephone between June and August 1988; 57 (9.4 percent) were excluded from this analysis because of incomplete information; their demographic characteristics and smoking status were similar to those completing the CES-D and acculturation scales for gender, age, acculturation, birthplace, education, and smoking status, but they were more likely to be unemployed. The 547 subjects completing the CES-D had a mean age of 35 years (SD = 12), 11 years (SD = 4.1) of education, and 59 percent were women. The mean duration of time living in the US for the foreign-born was 12.4 years (SD = 9.5) and the mean acculturation score for the entire sample was 2.4 (SD = 1.2). Overall smoking prevalence age-adjusted by the direct method[24] to the 1980 US Census[16] was 19 percent, with more men (29 percent) smoking than women (13 percent).

The overall mean level of depressive symptoms was 9.4 (95% CI = 8.6, 10.2), and 104 (19 percent) subjects scored 16 or greater on the CES-D. Table 1 shows the mean CES-D scores separately for men and women by demographic characteristics. Women reported a higher mean level of depressive symptoms than men for each category analyzed. Unemployment and less than high school education were also associated with a greater risk of depressive symptoms. Never smokers reported a lower mean level of depressive symptoms than current smokers or former smokers. The proportion of current smokers with a mean CES-D score ≥ 16 was 21.9 percent for men and 39.5 percent for women, compared to 11.8 percent and 18.5 percent, respectively, for never smokers.

The odds ratio (OR) of significant depressive symptoms (CES-D ≥ 16) by smoking status was evaluated using logistic regression analysis controlling for gender, acculturation, education, age, and employment status. Results, shown in Table 2, indicate that overall current smokers have a 70 percent greater risk of significant depressive symptoms than never smokers. The increased risk was present for both men and women. Former smokers do not have an increased overall risk of significant depressive symptoms although for women the risk is greater than for men.

Discussion

Among Latinos in San Francisco, current smokers have a modest increased risk of reporting significant depressive symptoms on the CES-D when compared to never smokers. Although unemployment and less years of education were associated with more depressive symptoms in this study, their effects were marginal compared to that of gender and smoking status. Marital status, social support and self-reported health status, which have been found to correlate with depressive symptoms in some studies,[9–11] were not determined as part of this survey and it is possible that these variables may partly account for our results.

[†] Significant depressive symptoms are defined as a CES-D score ≥16 (see text).

[‡] Never smokers were the reference group.

relationship exists between smoking and neuroticism.[25] The few specific studies on smoking and depression have found contradictory results. In a survey of 1,003 adults living in Los Angeles in 1979, Frerichs and colleagues[2] also found a significantly higher level of depressive symptoms as measured by the CES-D among smokers compared to nonsmokers (10.02 vs 8.76). In a study of 2,018 British men evaluated with a scale for psychoneurotic profile, Haines, *et al*,[3] also found that scores on the depression subscale (and the other four) were higher for smokers than nonsmokers. However, in both the above mentioned studies, when confounding factors were controlled the association of smoking and depression was no longer significant. A community survey of 1,209 men and women in New Zealand, using a scale similar to the British study, did find that depression was significantly greater among heavy smokers when compared to never smokers even when controlling for confounding factors.[4] Finally, a sample of 50 patients undergoing elective cardiac catheterization in St. Louis were evaluated for clinical depression and cigarette smoking was the only predictor variable associated with a diagnosis of depression.[26]

Although the causality between feeling depressed and smoking cannot be assumed from these cross-sectional data, recent prospective studies support such a link. Depressed adolescents 15 to 16 years of age in New York public schools were found to be more likely to be heavy cigarette smokers than non-depressed adolescents at ages 24 to 25 years.[5] Other suggestive evidence is from a clinical trial of clonidine as a pharmacologic adjunct to smoking cessation in 71 heavy smokers, which showed that 61 percent had a history of major depression and that this history had a significant negative effect on cessation regardless of treatment.[27]

It is possible that smokers report more depressive symptoms than nonsmokers because they are more willing to admit negative characteristics about themselves. As smoking becomes a less socially acceptable behavior smokers may become more depressed as a consequence, thus confounding the association observed in this study. However, if these findings are confirmed in other studies, smoking cessation interventions may need to integrate depression prevention and treatment components to maximize effectiveness.

Dental Office Practices for Tobacco Users: Independent Practice and HMO Clinics

HERBERT H. SEVERSON, PHD, ELIZABETH G. EAKIN, BS, VICTOR J. STEVENS, PHD, AND EDWARD LICHTENSTEIN, PHD

Abstract: Surveys of independent dental practitioners and health maintenance organization (HMO) dentists and their adult male patients in Oregon found that cessation information and advice was being given to tobacco-using patients, especially smokeless tobacco users, and that the tobacco users surveyed expressed interest in obtaining help to quit. Oral health providers expressed an interest in further training in how to help their tobacco-using patients to quit. (*Am J Public Health* 1990; 80:1503–1505)

Introduction

In 1985 it was estimated that over 12 million Americans ages 12 and older had used chewing tobacco or snuff (smokeless tobacco) in the past year[1]; among males who use smokeless, 43 percent used it almost daily.[2] Studies have shown correlations between smokeless tobacco use and gingivitis, gingival recession, leukoplakia, and oral cancers.[3]

In 1978, the House of Delegates of the American Dental Association (ADA) resolved that ADA members be encouraged "to undertake an educational effort to inform their patients of the systemic and oral health hazards of chewing tobacco and snuff." A 1964 ADA resolution had encouraged its members to advise their patients about the hazards of cigarette smoking.

Recent articles have reviewed dentists' involvement in smoking cessation counseling.[4,5] However, we are not aware of similar information about dentists' involvement with smokeless tobacco prevention. In this paper we report the results of two surveys of dentists, dental hygienists, and their adult male patients.

Methods

Independent Practice (IP) Survey

An explanatory letter was mailed to all practicing members of the Lane County Oregon Dental Society. Of the 114 dentists, 24 (21 percent) refused to participate and two were used as pilot offices. The study was conducted over a two-week period in 1988 during which time questionnaires were to be given to all male patients over 18 years of age visiting the dental office. Questionnaires were also completed by dentists and hygienists. The final questionnaire return rate for dentists was 83 percent (73/88). Data were also received from 65 hygienists and 806 adult male patients. Neither the base population of hygienists nor the population of eligible male patients was known.

HMO Survey

This study was conducted in the Kaiser Permanente Dental Care Program based in Portland, Oregon, which provided comprehensive dental care to 85,000 enrolled members. Seventy full-time dentists and 65 full-time dental hygienists were employed in seven fully staffed dental offices. The questionnaire return rate was 61 percent for dentists and 68 percent for hygienists.

Overall, 1,506 of age-eligible male patients (56 percent of the male patient population) completed the questionnaire. Observers making spot checks in the clinics noted that receptionists often failed to give the questionnaire to patients, but of those who did receive questionnaires more than 90 percent returned them to the reception desk as requested.

Results

Table 1 presents tobacco use and attitudes toward provider advice from each sample.

Table 2 summarizes the reported interactions with smokeless tobacco users and smokers for dentists in both settings. Most offer some kind of information and cessation advice. All types of information and advice were given more often with smokeless tobacco-using patients than with smoking patients. However, only a minority of providers have cessation materials available in their offices. Dentists tend to be more optimistic and comfortable when advising about smokeless use than about cigarette smoking. The majority of dental professionals in both surveys were interested in learning about a smokeless tobacco cessation program. The data from hygienists generally paralleled those of dentists.

The majority of dentists report being pessimistic about the effectiveness of their advice or the likelihood of a patient attempting a cessation clinic program (Table 3). The majority of hygienists reported the need for further training and patient resistance to referral as the most important obstacles.

Discussion

The results show that dentists and hygienists in both settings are concerned about patient tobacco use and inter-

ested in providing cessation information and/or advice. Unfortunately, dental professionals receive little training and have few materials available that would facilitate such actions. Dentists appear more comfortable giving advice to smokeless tobacco users than to smokers. The relevance of chew and snuff use to oral health is the most parsimonious explanation for this finding. The difference between smokeless tobacco use rates in the IP and HMO patient populations may be due to demographic differences, sampling differences, or personnel differences.

The patients surveyed reported receptiveness to cessation advice and, in fact, expect it from a dental professional. Direct feedback from a dentist or hygienist on oral health status, such as visually pointing to tobacco-associated oral lesions, gingival recession, or tooth staining, can produce a "teachable moment" wherein patients are receptive to cessation advice. This receptivity to advice from dentists and hygienists is supported by data from an in-depth interview study of smokeless tobacco users.[6]

Studies of physicians' advice to smoking patients have demonstrated modest but significant efficacy.[7–9] Recent reports indicate that dentists' direct advice also can have a significant effect.[11–14] Similar effects seem likely for smokeless tobacco. The obstacles to implementation include the need for specific cessation training for dentists and hygienists and self-help cessation materials for patients. Specific materials are now becoming available that will assist oral health professionals in getting more directly involved in advising patients who seek their help in order to quit the use of tobacco products.[14]

Evidence for Gonococcal Transmission within a Correctional System

KAREN H. VAN HOEVEN, MD, WALLACE C. ROONEY, JR., MD, AND STEPHEN C. JOSEPH, MD, MPH

Abstract: In a study to examine sexually transmissable disease occurring within a large correctional system where sexual activity is prohibited, 27 male inmates acquired culture-proven gonorrhea from in-jail sexual activity during a three-month period. These results provide evidence to encourage inmate education about the acquired immunodeficiency syndrome (AIDS) and to support condom distribution programs in correctional facilities. (*Am J Public Health* 1990: 80:1505–1506.)

Introduction

Studies reveal that up to 20 percent of male inmates engage in homosexual activity at some time during their imprisonment.[1] Research protocols which explore homosexual activity in jails and prisons generally use a subjective, questionnaire-type approach, asking prisoners whether they have participated in homosexual activity before or during incarceration.[1–7] Objective evidence for sexual activity occurring during imprisonment has been presented only in a few case reports which describe outbreaks of syphilis or gonorrhea occurring in prisoners incarcerated for prolonged periods.[8,9]

Sexual activity places inmates at risk for acquiring sexually transmitted diseases—including gonorrhea and the acquired immunodeficiency syndrome (AIDS). The risk of infection with the human immunodeficiency virus (HIV) among New York City prisoners during homosexual activity with other inmates is even higher than that of the general population, since studies have shown these inmates to have higher rates of HIV infection at admission to prison than the general population.[10]

Sexual activity is prohibited in many correctional systems, including that of New York City. Thus, the provision of condoms to inmates often is deemed unnecessary and objectionable by correction officials, since condom distribution would imply that rules prohibiting sexual activity are not enforced, or are unenforceable.[11] Yet from a public health perspective, condom distribution to inmates is important to enable inmates to protect themselves from sexually transmitted diseases, including AIDS. This study was designed to answer the following question: is there **objective** evidence that sexual activity occurs **regularly** in a large jail system?

Methods

In 1986, the correctional facilities of the New York City Department of Correction had a capacity to house over 12,500 inmates, and admitted more than 73,000 prisoners. The average daily census was almost always 100 percent or more of capacity. Most of the prisoners were detainees, staying for only a short period of time while awaiting trial or bail. Each prisoner received an admission history and physical exmination which included collecting information concerning a history of gonorrhea, dysuria, or urethral discharge and performing a urinalysis. Any newly admitted inmate who became suspect for gonorrheal infection after admission screening was examined, cultured, and treated for gonorrhea if clinically indicated.

For the months of October, November, and December 1986, the names, prisoner identification numbers, and dates of positive culture for all male New York City inmates with culture-proven gonorrhea were collected. From the files of the New York City Department of Correction, the date of admission to the jail was obtained for these prisoners. If an admission date preceded the date of positive culture by more than one week, the inmate's chart was reviewed and pertinent data were collected. These data included: date symptomatic, collection date and source (urethral, anal, and/or throat) of the specimen, and history of previous gonorrheal infections and treatment received, if any.

HIV Seroprevalence among Male IVDUs in Houston, Texas

MARK L. WILLIAMS, PHD

Abstract: HIV seroprevalence was 8.4 percent in a sample of 921 heterosexual male intravenous drug users in Houston, Texas who were not in drug treatment at the time of the study. Males who were Black, injected drugs daily, or had a history of syphilis had greater odds of being HIV positive than participants without those characteristics. (*Am J Public Health* 1990; 80:1507–1509.)

Introduction

The association between acquired immunodeficiency syndrome (AIDS) and intravenous drug use is well documented.[1] The primary means by which intravenous drug users (IVDUs) become infected with the human immunodeficiency virus (HIV), the cause of AIDS, are known.[2,3] However, the risk of an IVDU becoming infected with HIV is not uniform across racial/ethnic groups nor geographic locations.[4–6] As well, rates of HIV seroprevalence have been reported to vary among IVDUs due to the drug injected, frequency of injection, use of shooting galleries, injecting with strangers, the number of sexual partners, and a history of sexually transmitted diseases.[7–11]

The purpose of this study was to examine HIV seroprevalence rates among intravenous drug using males recruited from their natural environments in Houston, Texas. The majority of studies reporting HIV seroprevalence rates among IVDUs have been conducted in drug treatment, detoxification, or some other clinical setting.[2] Few studies have reported on the seroprevalence rates among intravenous drug injectors not in treatment.

Methodology

Subjects for this study were recruited from Houston's intravenous drug using population not in drug treatment. Participants were asked to respond to an interviewer administered survey covering demographic characteristic, drug use, and sexual behaviors. IV drug users were recruited from the city's three predominant racial/ethnic groups by trained, indigenous outreach workers. Three neighborhoods with known high incidences of intravenous drug use were targeted for outreach activities using targeted sampling.[12,13] Although targeted sampling is purposive, it is not random.

Study participants were required to be 18 years, have injected an illicit drug at least once during the six months prior to participation, and not have been in drug treatment for 30 days prior to participation. Outreach workers successfully recruited 1,279 men willing to be interviewed. Of that number, 81 percent agreed to have blood drawn for HIV testing. Only those respondents with complete surveys and HIV testing were considered for inclusion in the data set. Twenty-three participants were excluded because of sexual relationships with men during the previous six months. The resulting study sample of 921 males was 65 percent Black, 24 percent White, and 12 percent Hispanic (primarily Mexican American).

All variables used in the analysis, except HIV serostatus, are self-reported. A respondent's racial/ethnic classification was determined by his stated racial/ethnic identity. Drug use variables analyzed were frequency of injection, length of injected drug use, injection in a shooting gallery, sharing needles with a stranger, number of persons with whom needles were shared, and drug(s) injected. Frequency of injection was categorized as less than weekly, weekly, or daily depending on how often a respondent reported injecting during the six months prior to the interview. Drugs injected were categorized according to the reported drug(s) a respondent said he had injected during the six months before the interview. Respondents who said they injected more than one drug could either have injected the drugs alone or as mixtures.

Variables related to sexual behaviors which were examined were a self-reported history of syphilis, gonorrhea, herpes, and chlamydia. The number of sexual partners a respondent reported during the six months prior to participating in the study was examined.

HIV serostatus was determined by ELISA and Western Blot assays. Blood samples which were repeatedly positive on the ELISA test were screened using Western blot analysis. Samples were classified HIV positive if protein bands P24, P31, and EP41 or EP160 were present.

Univariate relationships were estimated using odds ratios and 95% confidence intervals. Significance was confirmed using Fisher's exact test (not shown).[14] To test the independence of significant univariate associations, a model of those relationships was analyzed using maximum likelihood method of logistic regression.[14,15] Coefficients are reported in independent odds ratios.

Results

HIV infection rates varied by race/ethnicity. As shown in Table 1, Black males had a seroprevalence rate of 10 percent. Seven percent of the White males were HIV positive. Black males were 2.80 times as likely to be HIV positive as Hispanic males.

Frequency of injection was found to be related to seropositivity. Less than weekly users had a 4 percent seropositive rate (Table 1). Eight percent of weekly users were HIV positive. Daily users had the highest number of positive test results, 11 percent. Associations between seroprevalence and self-reported history of syphilis, gonorrhea, herpes, and chlamydia were examined. Only a self-reported history of syphilis was significantly related to seroprevalence. Males who reported having had syphilis were 2.34 times as likely to be HIV positive as those who had not.

To test the independent association between race/ethnicity, frequency of injection, a past history of syphilis, and HIV seroprevalence logistic regression analysis was used. As shown in Table 2, these three variables are inde-

pendently associated with seropositivity. Each of the variables has approximately equal weight.

Discussion

The results of the analysis show that there is an association between race, frequency of injection, and a past history of syphilis. The relationship between frequency of injection and HIV infection did not vary by drug(s) injected. Heroin users injecting daily were just as likely to be HIV positive as cocaine users injecting daily. Although drug injected may have some pharmacological effect on the injecting behaviors of users, how often an IVDU is injecting, whatever the drug, would appear to be of greater importance. The association between a history of syphilis and HIV infection is far from clear. It would seem likely that the variable is indicative of risk of HIV infection due to behaviors associated with the condition.

HIV Seroconversion in Two Homosexual Men after Receptive Oral Intercourse with Ejaculation: Implications for Counseling Concerning Safe Sexual Practices

ALAN R. LIFSON, MD, MPH, PAUL M. O'MALLEY, NANCY A. HESSOL, MSPH, SUSAN P. BUCHBINDER, MD, LYN CANNON, AND GEORGE W. RUTHERFORD, MD

Abstract: Seroconversion for HIV antibody occurred in two homosexual men who reported no anal intercourse for ≥ 5 years and multiple episodes of receptive oral intercourse with ejaculation. Neither man reported intravenous drug use or receipt of blood products. The last antibody-negative specimen was also negative by the polymerase chain reaction and p24 antigen assays. All sexually active persons should be clearly counselled that receptive oral intercourse with ejaculation carries a potential risk of HIV transmission. (*Am J Public Health* 1991; 81:1509–1511.)

Introduction

Studies of homosexual and bisexual men have shown that anal intercourse, especially receptive anal intercourse with ejaculation, is the sexual practice associated with the greatest risk of human immunodeficiency virus (HIV) infection.[1-5] Although orogenital contact has not been statistically associated in these studies with HIV infection, many subjects engaged in multiple sexual practices, making a relatively lower risk more difficult to detect statistically.

Although transmission of HIV through receptive oral intercourse has been suggested in a few brief reports,[4,6,7] these reports have not provided extensive detail about the circumstances surrounding seroconversion. For this reason, there continues to be controversy about the safety of oral intercourse.

We report seroconversion for HIV antibody in two homosexual men who denied anal intercourse for ≥ 5 years and who engaged in multiple episodes of receptive oral intercourse with ejaculation.

Methods

The San Francisco City Clinic Cohort consists of 6,705 homosexual and bisexual men originally recruited from 1978 through 1980 for studies of hepatitis B.[8,9] Men enrolled in our prospective studies were recruited from this original cohort and are evaluated with an annual interview, including a sexual history by a trained staff member which asks about their activities in the preceding four months and for the entire period since their last interview. Study participants also receive an examination and medical history by a physician unaware of the subject's antibody status. Sera were tested for HIV antibody with the ELISA (Organon Teknika, Research Triangle, NC) and confirmed by both the Western blot and immunofluorescence assay (IFA).[10] Testing for HIV-DNA by the polymerase chain reaction (PCR) was conducted on DNA extracted from peripheral blood mononuclear cells using two different *gag* primers.[11] Sera were also tested for p24 antigen (Coulter Immunology, Hialeah, FL).

Results

For both men who seroconverted, in the two years preceding seroconversion at least three specimens were negative by the ELISA assay; the last pre-seroconversion specimen was also negative by PCR and p24 antigen assays. The first post-seroconversion specimen was positive for HIV antibody by the ELISA, IFA and Western blot assays. Both men were also HIV-antibody positive on repeat testing of the first post-seroconversion specimen (including a second serum sample drawn at the same time), as well as on at least one follow-up specimen drawn between four and nine months later.

Both men reported no insertive or receptive anal intercourse for at least five years preceding the estimated date of seroconversion; this history was supported by three previous interviews. Both men also denied use of intravenous drugs,

The AIDS-Related Experiences and Practices of Primary Care Physicians in Los Angeles: 1984–89

CHARLES E. LEWIS, MD, AND KATHLEEN MONTGOMERY, PHD

Abstract: Telephone interviews of random samples of Los Angeles primary care physicians in 1984, 1986, and 1989 obtained information about their AIDS-related practice experiences, and sexual history taking. Data from mid-1989 reveal almost 74 percent have worked up at least one patient for AIDS or HIV infection in the past six months and 39.5 percent are caring for at least one patient with AIDS or AIDS-related complex. Self-reported use of appropriate sexual history questions has improved substantially over this five-year period. (*Am J Public Health* 1990; 80:1511–1513.)

Introduction

There has been growing speculation, based primarily upon surveys of physicians' attitudes, that a significant proportion of doctors might fail to provide care to patients found to be infected with the human immunodeficiency virus (HIV) and/or who developed acquired immunodeficiency syndrome (AIDS).[1,2]

Over the past six years, we have conducted three telephone surveys of random samples of primary care physicians in full-time office-based practice in Los Angeles, California (January 1984,[3] summer 1985,[4] and summer 1989). Data presented here illustrate changes over this period in physicians' experiences with patients at risk or infected with HIV.

Methods

Stratified random samples of internists, family practitioners, and general practitioners were drawn to reflect the relative proportion of each of these groups practicing in Los Angeles County. The samples were drawn from data tapes provided by the American Medical Association Physician Masterfile, containing listings of all primary care physicians in full-time office-based practice in Los Angeles—a pool of about 5,000 physicians.[5]

Results

Response Rates and Characteristics of the Sample

The response rates for all three surveys have been above 60 percent; the most recent survey resulted in a 77 percent response rate. These response rates are calculated using as the denominator all physicians actually contacted (see Table 1).

Examination of the demographic characteristics of respondents versus nonrespondents during each survey period has revealed no obvious source of bias. The increase in the proportion of women interviewed over the past five years reflects the growing number of women primary care physicians practicing in Los Angeles County; for Los Angeles as

a whole, the proportions are: 11 percent in 1984, 14 percent in 1986, and 16 percent in 1989.[5]

AIDS-Related Practice Experiences

The proportion of physicians who, within the six months prior to being interviewed, had worked up or referred a patient for work up of possible HIV infection, including AIDS, has almost tripled, growing from 27 percent to over 73 percent in the five years between 1984 and 1989. Also, the proportion of physicians who have at least one patient in their practice with AIDS has grown from less than 1 percent in 1984 to almost 40 percent in 1989. While 29 percent of primary care physicians surveyed in 1989 had between one and five AIDS patients in their practice, a small group of these physicians (3 percent) were caring for 15 or more patients with AIDS (see Table 2).

Sexual History Taking Questions

Physicians were asked if they took sexual histories on all their new patients. Those responding affirmatively were asked, "What do these questions cover?"

As Table 2 indicates, the proportion of physicians who volunteered they ask about the sexual orientation of their patients has doubled during this five-year interval, with close to half the physicians in 1989 saying they asked for such information. The proportion reporting they ask patients about the number of sexual partners has tripled in the five-year period.

Physicians' Attitudes

Physicians were also asked the extent to which they think the average physician is uncomfortable discussing sexual matters with homosexual patients. In an attempt to avoid only socially acceptable responses, the question was phrased in general terms, rather than asking about the doctor's own level of discomfort. Table 2 shows that these figures have changed little over the past five years, with nearly three-fourths estimating that their colleagues have moderate or considerable discomfort. The estimated discomfort of others is unrelated to physicians' own reported AIDS-related experiences.

Discussion

The data from these three surveys suggest that, as a group, a significant number of primary care physicians in Los Angeles have responded to the growth in the number of AIDS cases by accepting responsibility for the care of patients with AIDS or AIDS-related complex. Unfortunately, these data do not allow us to estimate the extent to which the patients under care of these physicians represent their established patients who have developed AIDS, or whether these are new patients in the practice. Nor can we distinguish among the 60 percent of physicians who have no AIDS patients in their practice how many have refused to care for a patient with AIDS, as contrasted to those who merely have not yet encountered any patients with AIDS.

It may be reassuring to those responsible for funding physicians' education about AIDS that physicians' awareness of the content of a sexual history has improved substantially during the past five years.

While the data on physicians' sexual history taking is self-reported, there is evidence that their awareness of some key questions that should be asked has increased. Knowledge of these is a prerequisite to their use, but we have no data from patients to validate that these were asked. Despite this improvement, a majority of primary care physicians apparently are not asking questions essential in assessing sexual risks.

The persistent belief over time among physicians that their colleagues are uncomfortable in dealing with homosexual patients remains puzzling, given the increases in contact with AIDS patients and reports of more comprehensive sexual histories. Lacking additional data, we were unable to determine whether physicians' perceptions of colleagues' discomfort is unrelated to their own feelings, or that feelings of discomfort simply are not strong predictors of the willing-

Behavioral Change in Longitudinal Studies: Adoption of Condom Use by Homosexual/Bisexual Men

Jill G. Joseph, PhD, S. Maurice Adib, MD, MPH, James S. Koopman, MD, and David G. Ostrow, MD, PhD

Abstract: We compared reporting serial cross-sectional prevalence of sexual behavior over time, to reporting individual patterns of behavioral change in a cohort of homosexual men at a six-month interval. Aggregate prevalence rates underestimated the magnitude of change to safer practices, and failed to provide information on relapse to less safe practices. We conclude that it is important to report data based on individual fluctuations in behavior for the evaluation of change over time. (*Am J Public Health* 1990; 80:1513–1514.)

Introduction

During the past few years, the issue of condom use by homosexual/bisexual men in response to the threat of acquired immunodeficiency syndrome (AIDS) has been addressed in several reports from diverse geographic areas. While some reported cross-sectional findings,[1] others have dealt with the more complex task of describing longitudinal behavior patterns.[2] A recent letter by Kelly and St. Lawrence[3] has highlighted the difficulty of documenting relapse to unsafe sex practices through serial cross-sectional studies that mainly monitor relative increases (or decreases) in sexual behavior prevalence.

We have been surveying adoption and maintenance of safer sexual practices, most recently with regard to condom use in receptive anal sex, in a cohort of homosexual/bisexual men in Chicago. This brief report utilizes some findings from that cohort to highlight methodological issues related to reporting behavioral change in longitudinal studies.

Methods

Participants in the Chicago Multicenter AIDS Cohort Study are concurrently enrolled in a longitudinal behavioral and psychosocial investigation. Detailed methods of recruitment and assessment have been described previously.[4,5] Self-administered questionnaires are completed semi-annually after each visit to the study center. Men have already participated in nine such visits and data collecting is ongoing. At visit 4 (V4) in February 1986, 729 men completed a new section of the questionnaire dealing with condom use in receptive anal sex. At visit 5 (V5), complete data were available for 642 men. A total of 601 men completed this section at both visits. Dropout effect was negligible, as participants at V4 and/or V5 did not differ significantly with regard to baseline sociodemographic or behavioral variables. Men in the V4-V5 cohort were predominantly White (89 percent), had a mean age in 1984 of 34.5 years, a mean educational attainment of 16.4 years, and a mean annual income in 1984–85 of $26,300. Forty percent of them were HIV seropositive by V5.

Participants described consistency of condom use during receptive anal sex (always, sometimes, never) with various types of sexual partners, ranging from those with whom they had a steady relationship to anonymous contacts. Two methods for analysis of these data are considered below. The first one defines four levels of condom use in receptive anal sex, from most to least safe.

1. no receptive anal sex;
2. consistent condom use with all partners;
3. inconsistent condom use;
4. no condom use.

This method was applied in serial cross-sectional analyses at V4 and V5. The second method includes these same four components considered in terms of behavioral consistency between V4 and V5. For men in each of the above categories at V4, subsequent behavior at V5 was described in one of three ways:

1. maintenance of the same behavior;
2. change to any less safe practice;
3. change to any safer practice.

Results

Table 1 reports aggregate serial cross-sectional findings from V4 and V5. It shows a slight increase in the prevalence of safer sexual practices (no receptive anal sex or consistent condom use) with some decrease in no condom use. Overall, change reported as aggregate data suggests that prevalence of

Joseph, PhD, Associate Professor, Department of Epidemiology, School of Public Health, University of Michigan, 109 Observatory, Ann Arbor, MI 48109. This paper, submitted to the Journal March 29, 1989, was revised and accepted for publication April 22, 1990.

TABLE 1—Serial Cross-Sectional Prevalence of Condom Use in Receptive Anal Sex at Visit 4 (V4) and Visit 5 (V5)

	V4 N (%)	V5 N (%)
No receptive anal sex	375 (52)	341 (53)
Consistent condom use	66 (9)	78 (12)
Inconsistent condom use	96 (13)	94 (15)
Condoms never used	192 (26)	129 (20)
Total	729	642

safer sexual practices increased somewhat over a six-month interval.

A second approach to assess risk reduction takes account of intra-individual stability or instability in behavior and is shown in Table 2. Prevalence of intra-individual change in the V4-V5 cohort was 41 percent, much higher than suggested in Table 1. Among those maintaining the same behavior, a majority maintained safer practices, but 49 percent of those never using condoms maintained such a practice over six months. Intra-individual change to safer sexual practices was reported in 24 percent of the cohort, but this approach revealed relapse to less safe sex in 17 percent of participants.

TABLE 2—Individual Patterns of Maintenance and Change in Safer Sexual Practices in Receptive Anal Sex Over a Six-month Period

Practices at V4	Base at V4 N (%)	Maintained at V5 N (%)	Changed to less safe N (%)	Changed to safer N (%)
No receptive anal sex	307 (51)	239 (78)	68 (22)	— —*
Consistent condom use	56 (9)	24 (43)	13 (23)	19 (34)
Inconsistent condom use	85 (14)	27 (32)	23 (27)	35 (41)
Condoms never used	153 (26)	62 (49)	— —*	91 (59)
Total (N = 601)	601	352 (59)	104 (17)	145 (24)

*Such change was not possible at V5, as participants were already at most extreme categories at V4.

Discussion

Intra-individual fluctuations in individual risk-relevant behaviors have been reported in many longitudinal studies of homosexual men.[6] As early as 1985, a report from San Francisco noted that over the course of one year, approximately half the men observed in one cohort had changed their behavior, from completely or probably safe to probably or definitely risky.[7] Aggregate measures, as we demonstrated, can underestimate the magnitude of change to safer sexual practices, but even more important, they often fail to convey important information on adoption, maintenance and relapse in individual patterns of behavior over time. They are therefore, an essential part of evaluating long-term behavioral change, whether the change is related to HIV/AIDS or to other conditions.

Seat Belt Use in Cars with Air Bags

ALLAN F. WILLIAMS, PHD, JOANN K. WELLS, BS, AND ADRIAN K. LUND, PHD

Abstract: Seat belt use was observed in 1,628 cars with air bags and manual belts and 34,223 cars with manual seat belts only. Sixty-six percent of drivers in cars with air bags wore seat belts compared to 63 percent of drivers in cars with manual belts only. The study found no evidence for the speculation that drivers with air bags will reduce their seat belt use because they believe an air bag alone provides sufficient protection. (*Am J Public Health* 1990; 80:1514–1516.)

Introduction

Federal regulations in the United States require that all passenger cars manufactured in 1990 and after be equipped with automatic restraints. During the phase-in period for this requirement, manufacturers had to equip 10 percent of their passenger cars with automatic restraints in the 1987 model year, 25 percent in 1988, and 40 percent in 1989. Two types of restraint systems have been used to meet the requirement: air bags that inflate automatically in frontal crashes, and seat belts that automatically fasten around occupants when they enter or start the car. When the automatic restraint requirement was being phased in, most manufacturers met it by installing automatic seat belts rather than air bags. Increasingly, air bags have been offered. The percentage of automatic restraint cars sold with air bags was about 10 percent in the 1987 model year and is projected to be 30 percent in

1990 models.[1] Based on announced plans of manufacturers, air bags will be the predominant automatic restraint offered in the 1990s.

Cars with driver side air bags (as well as those few that currently have right front passenger side air bags) are also equipped with manual lap and shoulder belts to meet federal requirements for lateral and rollover crash protection. Together, air bags and lap/shoulder belts provide the most effective restraint protection available. There has been concern that occupants might be less likely to use a manual lap/shoulder belt in vehicles with air bags than in cars that had *only* manual lap/shoulder belts, because they may erroneously assume that the air bag alone provides full or sufficient crash protection. To the extent that this occurred, it would lessen the crash protection otherwise achievable through the combination of air bags and seat belts. To provide information on this question, a survey of belt use in late model cars with and without air bags was undertaken.

Methods

Seat belt use by drivers and right front seat passengers was observed in four metropolitan areas in the fall of 1989. The areas surveyed were metropolitan Chicago, Los Angeles, Philadelphia, and the Maryland and Virginia suburbs of Washington, DC. In each of these areas, seat belt use is required by state law.

To provide a sample of late model cars, observations were restricted to cars with high center mounted brake lights. These lights have been required on all new cars beginning with the 1986 model year. (Some 1985 cars also had high center mounted brake lights, but these were subsequently eliminated from the study sample.)

In each metropolitan area, observations were made at 64 sites, typically intersections with traffic lights. The sites were distributed throughout the metropolitan regions but were concentrated in affluent areas to maximize the likelihood of observing late model cars. Observations at a site were made during either morning (7:00–9:30 am) or evening (4:00–6:30 pm) rush hours. Sites and observation procedures were the same as those used in a previous survey.[2]

In addition to observing shoulder belt use, observers recorded license plate numbers of the vehicles, which were used to obtain vehicle identification numbers (VINs) from motor vehicle departments in Illinois, California, Pennsylvania, Maryland, and Virginia. VINs provide information on car model, model year, and type of restraint system. Using this technique, errors in identifying the vehicle observed are possible only in rare instances, such as the license number was recorded incorrectly or the owner had transferred the license plate from another car to the one observed and the department of motor vehicles had not yet updated their files.

Results

Seat belt use was observed in 45,466 1986–90 model year cars; complete VIN information was available for 97 percent of these vehicles. Of these 44,102 cars, 1,628 were equipped with air bags and lap/shoulder manual belts; 34,223 were equipped with manual lap/shoulder belt systems only. Driver belt use rates were about the same in cars with and without air bags (Table 1). Overall, 66 percent of drivers in cars with air bags used seat belts compared to 63 percent of drivers in cars with manual belts only. Belt use rates of drivers with and without air bags were about the same in each metropolitan area, although belt use rates were substantially higher in Los Angeles and the Washington, DC area than in Chicago and Philadelphia.

TABLE 1—Driver Manual Belt Use in Cars with Air Bags and in Cars with Manual Belts Only, by Metropolitan Area

Metropolitan Area	Percent (N) Using Belts	
	Air Bag Cars	Manual Belt Cars
Chicago	51 (355)	53 (10441)
Los Angeles	73 (684)	71 (8540)
Philadelphia	59 (317)	57 (8521)
Washington, DC	75 (272)	76 (6721)
Total	66 (1628)	63 (34223)

Only a few of the observed cars had a right front passenger air bag and a right front passenger present (N = 22); 50 percent of these passengers were belted. For right front passengers in cars with driver side air bags only, belt use was 56 percent (N = 235) compared to 54 percent (N = 5473) in cars without air bags. Belt use rates for drivers in cars that had right front passengers present was 64 percent in cars with driver side air bags only and 59 percent in cars without air bags.

Table 2 presents driver belt use in cars with and without air bags by manufacturer. Driver belt use was as high or higher in air bag equipped cars as in cars without air bags except for the Chrysler models, which had a slightly lower use rate.

Table 3 presents driver belt use in cars with and without air bags for specific models of cars that were observed in sufficient numbers to make such comparisons. These data indicate that belt use was usually about the same or slightly higher in cars with air bags.

Cars with air bags in the study sample were on average newer than cars with manual belts only. Table 4 presents data on cars with and without air bags by model year. Belt use increased slightly by model year both for cars with and without air bags. For each model year, driver belt use was as high or higher in air bag cars as in cars without air bags.

Discussion

There is no evidence from this survey that the presence of an air bag lessens the likelihood of using a seat belt. Manual seat belt use by drivers of cars with driver side air bags was about the same as for drivers of late model cars that did not have air bags. In cars with drivers and right front passengers

TABLE 2—Driver Manual Belt Use in Cars with Air Bags and in Cars with Manual Belts Only, by Manufacturer

present, driver belt use was eight percentage points higher than passenger belt use in cars with driver side air bags and five percentage points higher in cars with manual belts only. If air bags reduced belt use, driver belt use in these air bag equipped cars would have been much lower relative to passenger use.

Manual belt use rates were higher than average in this survey because the observations were restricted to late model cars and were concentrated in affluent areas in states with laws requiring belt use. All of these factors elevate seat belt use.[3,4] Most of the nation's population (89 percent) is now covered by belt use laws; belt use rates in cars with and without air bags would be expected to be lower in the 14 remaining states without laws. Nevertheless, many drivers and right front passengers observed were not using seat belts even though required by law to do so. An important goal is to increase seat belt use both in cars with and without air bags.

Age, Sex, and Road-Use Patterns of Motor Vehicular Trauma in Rhode Island: A Population-Based Hospital Emergency Department Study

IAN R.H. ROCKETT, PHD, MPH, ELLICE S. LIEBERMAN, MD, DRPH, WILLIAM H. HOLLINSHEAD, MD, MPH, SANDRA L. PUTNAM, PHD, AND HENRY C. THODE, PHD

Abstract: Population-based hospital emergency department data on motor vehicle traffic trauma in Rhode Island, 1984–85, are analyzed by age, sex, and road-use status. Annualized rates of overall and severe trauma were 1,195 cases (95% confidence interval [CI] = 1,164, 1,225) and 102 cases (95% CI = 94, 111) per 100,000 population, respectively. Overall and severe rates peaked at ages 15–24 years. Male rate excesses were most pronounced for motorcycle and pedal cycle trauma. (*Am J Public Health* 1990; 80:1516–1518.)

Introduction

Population-based data on nonfatal motor vehicular trauma are not collected routinely. In population-based studies, case selection has typically been restricted in terms of injury diagnoses, road-use status, and age of population.[1–5] An exception is the Northeastern Ohio Trauma Study, in which a comprehensive sample of motor vehicular trauma cases was drawn from regionwide hospital emergency department records.[6] Adopting a similar methodology, the Rhode Island Department of Health instituted a motor vehicular trauma surveillance system.[7] This report documents patterns of motor vehicle traffic trauma rates for Rhode Island by age, sex, and road-use status.

Methods

Cases represent a 25 percent systematic sample of first encounter motor vehicle traffic trauma patients treated during 1984 and 1985 in the emergency departments of the 12 Rhode Island civilian, acute care, nonpsychiatric hospitals with an emergency facility. They include only Rhode Island patients and fatalities (on RI roads) with known age and sex, who were or could be assigned an ICD-9CM external cause of injury

code (E-code) within ranges E810–E816 and E818–E819. Additional information on the methodology is available elsewhere.[7,8]

Numerators in the overall rates represent annual averages estimated from emergency department cases weighted for the inverse of the sampling fraction. Severe cases were a combination of weighted hospital nonfatal admissions and total fatalities; their initial age groups were collapsed in order to address the small numbers. For both sets of rates, denominators are mid-period age- and sex-stratified population estimates that were based on the 1980 Census for Rhode Island[9] and an official projection of the State population for July 1, 1985.[10]

Results

Overall Trauma

Sample cases numbered 6,268; 92 percent involved Rhode Island residents, and constituted the focus of this report. The estimated 1984–85 average annual number of motor vehicular trauma cases among Rhode Island residents was 11,538, and the corresponding rate was 1,195 cases per 100,000 population (Table 1). Motor vehicle occupants contributed three-fourths of the cases.

The estimated annualized motor vehicular trauma rate for males was 1,311 per 100,000 population, and that for females was 1,080. Irrespective of sex, the rates peaked at ages 15–19 years.* Although varying by sex, this age group also registered the highest rates in the motor vehicle occupant, motorcyclist, and other/unspecified road-use categories. Rates for the pedestrian, pedal cyclist and motorcyclist categories peaked at ages 5–9, 10–14, and 20–24 years, respectively.*

Rates were lowest at the extremes of the age spectrum, and were 21 percent greater for males than females. Male predominance was most evident in the motorcyclist category, where the relative risk exceeded five.

Severe Trauma

The estimated annualized rate of severe trauma (fatalities and hospital admissions) was 103 per 100,000 population (Table 2); 64 percent were in the motor vehicle occupant category; pedestrian and motorcycle trauma cases together comprised almost 30 percent. Respective estimated rates for males and females were 133 and 74 per 100,000 population.

Regardless of sex, the severe trauma rate reached a zenith at ages 15–24 years, and was lowest at ages 0–14 and 45–64. The highest rates in the motor vehicle occupant, motorcyclist and other/unspecified road-use categories were registered in the 15–24 age group. Rates peaked at 0–14 years in the pedal cyclist category. There was a bimodal distribution in the pedestrian category, with rates highest at the extreme ages. Males manifested an 80 percent greater risk of sustaining severe motor vehicular trauma than females. In the motorcyclist category, the overall relative risk for males was nine.

Discussion

Overall trauma rates are probably underestimated here because cases involving individuals who refrained from seeking treatment or were self-treated and those treated in out-of-state hospitals or other health care facilities were outside the study population. Estimated severe trauma rates more closely approximate true rates than do the rates of overall trauma, since they are less likely to be influenced by differential discretionary care-seeking behavior among population sub-groups.

Although the Rhode Island study is more recent than the Ohio study,[6] comparisons are instructive. During the respective time frames of these two studies, neither population was covered by a motorcycle helmet law or by a universal seat belt use law. For every motor vehicle traffic trauma fatality among Rhode Island residents, there were an estimated 11 hospital admissions and 130 patients treated in hospital emergency departments. Respective figures for Northeastern Ohio were one, 11, and 137. Other remarkable similarities are apparent in patterns of overall trauma rates by age, sex, and road-use status as, for example, the excess rates for males and young adults. Severe trauma rates were not computed in the Ohio study.

Experience from the two studies underscores the need for comprehensive E-coding of motor vehicular trauma in hospital records. Also essential in identifying high-risk populations, and designing, targeting, and evaluating appropriate interventions, is compilation and analysis of environmental and behavioral data, such as road configurations at trauma sites and motorist usage of safety devices, alcohol, and other drugs.

Rhode Island was the second state in the nation to enact a child restraint use law. The current data were collected as the founding activity of a nascent injury control unit at the Rhode Island Department of Health with the expectation that they would be useful in advocacy for, and evaluation of, a universal seat belt use law. Unfortunately, Rhode Island remains in the minority of states without such a law. Ironically, absence of a law enabled the Rhode Island

TABLE 1—Number and Percentage of Resident Cases in a 25% Motor Vehicular Trauma Sample by Road-use Status for Persons Treated in Hospital Emergency Departments, and Associated Annualized Rates per 100,000 Population, Rhode Island, 1984–85

	Sample			
Road-use Status	No.	%	Rate	95% Confidence Interval
Motor vehicle occupant	4,319	74.9	894	868, 921
Motorized cyclist	318	5.5	66	59, 73

*Detailed age-, and sex- and road-use-specific data pertaining to both overall and severe motor vehicular trauma are available from the first author upon request.

TABLE 2—Number and Percentage of Resident Motor Vehicular Trauma Fatalities and Nonfatal Hospital Admissions by Road-use Status, and Associated Annualized Rates per 100,000 Population, Rhode Island, 1984–85

Road-use Status	No. Fatalities*	No. Admissions†	%‡	Rate	95% Confidence Interval
Motor vehicle occupant	84	295	63.8	65	58, 73
Motorized cyclist	18	61	13.2	14	10, 17
Pedal cyclist	4	10	2.2	2	1, 4
Pedestrian	50	67	16.1	16	13, 20
Other/unspecified	21	18	4.7	5	3, 7
Total	177	451	100.0	103	94, 111

*Fatalities represent a complete enumeration of residents who died due to motor vehicular trauma sustained on in-state public roads in 1984 or 1985. The data source is the Division of Vital Statistics, Rhode Island Department of Health.

†Admissions derive from resident cases in a 25% sample for persons treated in hospital emergency departments for motor vehicular trauma. The 35 fatal emergency department cases are excluded.

‡Percentages are based on a combination of total fatalities and weighted nonfatal admissions. The weights are the inverse of the sampling fraction; four.

population to serve as an external control in an ongoing epidemiologic evaluation of the New York State law.[8,11]

The surveillance system which is described here provided data for an alcohol-related injury intervention study.[12] Rhode Island has now established an Office of Injury Control and implemented a variety of interventions aimed at reducing both vehicular and nonvehicular trauma. E-coding by all hospitals is a top priority of the Office, and geographic study of trauma sites is also planned. Both seat belt and helmet use bills were introduced again in the 1990 session of the State Legislature by the Governor.

Evaluation of the Efficacy and Cost Effectiveness of Health Education Methods to Increase Medication Adherence among Adults with Asthma

Richard A. Windsor, PhD, MPH, William C. Bailey, MD, James M. Richards, Jr., PhD,
Brynda Manzella, MPH, Sen-Jaw Soong, PhD, and Michael Brooks, EdD

Abstract: We randomized 135 adult asthma patients to a control group, and 132 patients to an experimental group which received a special health education intervention. Four adherence measures were documented at baseline and 12-month follow-up: correct inhaler use, inhaler adherence, medication adherence, and total adherence rating. Costs to routinely deliver the intervention were $32.03/patient. Experimental group patients exhibited a significantly higher level of improvement in adherence (44 percent) than control group patients (2 percent). (*Am J Public Health* 1990; 80:1519–1521.)

Introduction

The prevalence of asthma among adults in the United States is 3–6 percent.[1–3] There are over 500,000 hospitalizations and 3,500 deaths from asthma per year.[3] Multiple studies of adults with asthma confirm regimen adherence levels of only 30–40 percent.[4–7] Educational intervention studies have reported methodological problems, used small sample sizes, lacked cost analyses, and presented inconclusive results.[8] This evaluation study was designed to document *efficacy* (the level of behavioral impact produced by a health education program with optimal resources) and *costs* (personnel and materials needed to routinely deliver the program).

Methods

The study was conducted at a university-based comprehensive pulmonary medicine clinic. Patients who had a primary diagnosis of asthma, used medications daily, and met the following diagnostic criteria were eligible: recurrent episodes of wheezing or dyspnea; objective evidence of significantly increased airway resistance during episodes; and improvement in the airway when symptom-free.[9–10] Of the 280 adults $\geq$ 17 years meeting the criteria screened between April 1986 to March 1987, 267 (95 percent) participated.

Following informed consent and baseline assessment, 135 patients were randomized to a control group, and 132 patients to an experimental group. Prior to randomization, patients were stratified by level of asthma severity within each of 11 physician practices (see Appendix). Using pilot study data, an estimated possible improvement in adherence of 20 percent or more for 12 months,[4–8,11–15] and an anticipated 10 percent attrition rate, we defined a need for at least 120 patients in each study group.[16,17]

Health Education Intervention

The experimental group received a peak flow meter and a standardized program from a health education specialist:

- A 30-minute one-to-one session with instruction on peak flow meter use, inhaler use skills, and use of *A Self-Help Guide to Asthma Control;*[18]
- A 60-minute asthma support group session of four to six patients and asthma control partners, and
- Two brief telephone reinforcement calls within one month of the group session.

One-to-one discussions and a review of all methods and materials were conducted with clinic nurses and all 11 participating pulmonary physicians. Four group sessions with patients were held to develop the intervention. All educational components and evaluation methods were pilot tested.

Measurement

All patients received a baseline and 12-month follow-up medical and behavioral assessment including four behavioral outcomes: 1) correct inhaler use, 2) inhaler adherence, 3) medication adherence, and 4) total adherence rating. A 10-item observational checklist documented inhaler use (IU) and skill.[19] Medication adherence (MA) and inhaler adherence (IA) were assessed using instruments adapted from the literature.[20–22] Psychometric analyses (Cronbach Alpha) confirmed adequate reliability: r (MA) = .69, r (IA) = .64, and r (IU) = .78. Items analyses confirmed minimum item discrimination coefficients: $r \geq .20$. A Total Adherence Score was derived by combining patient scores on the medication and inhaler adherence scales.

Over 85 percent of the patients used an inhaled bronchodilator and continuous theophylline. Theophylline levels were analyzed on the two follow-up assessment days to indirectly corroborate patient adherence reports. Patients were informed that their theophylline level would be analyzed to assess adherence. While theophylline level is an imperfect measure of adherence and does not reflect adherence to non-theophylline medications, behavioral studies of adults who know a method is available to validate self-reports document a significant reduction in deception rates (bogus pipeline or pipeline effect).[23,24]

Behavioral Intervention Results

A comparison of the 13 patients who refused (5 percent refusal rate) versus the 267 who participated confirmed no baseline differences by gender, race, age, education, and asthma severity. Data in Table 1 confirm group equivalence at baseline. Thirty-four of the control group patients (25 percent) and eight of the experimental group patients (6 percent) were lost to follow-up. Analyses of baseline data confirmed that the 42 dropouts were not significantly different from the 238 participants. Within the intervention group, use of the *Asthma Guide*[18] was reported by 124 patients (94 percent); 110 (89 percent) participated in the group session

FIGURE 1—Behavioral Impact by Type and Study Group

and 124 patients (94 percent) received both reinforcement calls.

The behavioral impact of the intervention is presented in Figure 1. Using a 95% confidence interval (CI) to evaluate differences between rates of group improvement, a consistent pattern of adherence was confirmed for a 12-month period. Significant improvements for the intervention group in inhaler skills use (CI = .29, .61), inhaler adherence (CI = .24, .50), medication adherence (CI = .31, .57), and total adherence score 100 percent adherence (CI = .28, .56) were observed. Little behavior change was observed in the control group.

Cost Estimation and Analysis

Patient time and intervention development costs were not used to compute program costs. While an MPH-health education specialist provided the intervention, a nurse would be the typical provider. We used a salary of $25,000 plus a fringe benefit rate of 20 percent to estimate nursing cost: $30,000 per year/2080 hr = $14.42/hr. Total personnel time costs were $24.30: Component #1 = $7.21, Component #2 = $14.42 and Component #3 = $2.40. The *Asthma Guide*[18] cost $8.00 for a Total Intervention Cost = $32.03/patient. The total control group costs for a 10-minute general discussion about the importance of adherence and two brief follow-up contacts for a total of 15 minutes were $3.61/patient.[25,26] Cost analyses presented in Table 2 confirmed the need to allocate resources to significantly increase patient adherence.

Discussion

The increases in adherence observed in our intervention group exceeded those of previous reports. While some proportion of patient self-reports of adherence may represent a "social desirability" response, psychometric analyses indicated good measurement of behavioral impact. Our high recruitment rate confirmed that adults with asthma are interested in taking an active role in their self-management and will participate in a health education program integrated into routine asthma care. Near unanimous positive anecdotal comments about the intervention by nurses, physicians, and patients were observed. Feasibility, patient and provider acceptance was very high. From an administrative and programmatic perspective, our experience indicated that this type of intervention has potential for adaptation by other asthma programs. However, in our attempt to maximize efficacy, an intervention was provided which may be too resource intensive and costly for other asthma care sites.

While the methods and results reported here and elsewhere were encouraging,[8,18,27] future health education research needs to evaluate the impact of a streamlined health education program on health services utilization, e.g., am-

This research was supported by Grant ROI HL 31481-02 from the Division of Lung Diseases, National Heart, Lung, and Blood Institute.

The findings were presented at the 117th annual meeting, American Public Health Association, October 25, 1989, Chicago, Illinois.

APPENDIX

Dear Doctor,

As part of the Asthma Education Project, the severity of your patient's asthma based on their current regimen is needed.

Please circle the appropriate severity level:

0—Mild—generally wheeze-free, responds well to medication.
1—Moderate—occasional wheezing with periods of significant wheezing.
2—Severe—constant wheezing, does not respond well to medications, steroid dependent

Please encourage your patient to participate in the Asthma Education Project.

Thank you,

The Asthma Project Staff

©AMERICAN JOURNAL OF PUBLIC HEALTH
December 1990
Volume 80

The *American Journal of Public Health*, published monthly, is the official Journal of the American Public Health Association. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy.

The Journal, established in 1911, publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Neither the Association nor the Editors assume responsibility for the opinions expressed by authors of papers published or quoted in this Journal. Copyright 1990 by the American Public Health Association, Inc. Second class postage paid at Washington, DC and additional mailing offices.

Subscription price of the *American Journal of Public Health* is $80 per year domestic; $120 per year foreign (air mail); $10 prepaid for single copies of an issue or supplement from the American Public Health Association, 1015 Fifteenth Street, NW, Washington, DC 20005.

HISPANIC HEALTH AND NUTRITION EXAMINATION SURVEY, 1982–84:

Findings on Health Status and Health Care Needs

FOREWORD

In 1986 the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO) established the Hispanic Health Research Consortium (HHRC) to spearhead analysis of the landmark Hispanic Health and Nutrition Examination Survey (HHANES). Conducted by the National Center for Health Statistics (NCHS), HHANES was the first representative survey to provide physical examination information on the health and nutritional status of Mexican Americans, Puerto Ricans, and Cuban Americans.

HHRC was established when COSSMHO entered into an agreement with the Office of the Assistant Secretary for Health (OASH) in the US Department of Health and Human Services and the National Center for Health Statistics to facilitate research by nongovernment sources on the data from the HHANES. Two rounds of competitive grants were awarded by COSSMHO to establish a network of eight university and community-based research teams. COSSMHO coordinated the research of this network, provided technical assistance, convened meetings of HHRC researchers, and disseminated information nationally to researchers interested in conducting HHANES analyses.

The unique partnership between COSSMHO, OASH, NCHS, and university and community-based researchers ensured that there would be: support for HHANES research in critical areas; appropriate outreach to Hispanic researchers and those who have developed a reputation for their work on health in Hispanic communities; support for graduate level students to conduct research on the health status of Hispanic communities; and hopefully the development of a pool of future research talent. The establishment of the Hispanic Health Research Consortium has moved the analysis of Hispanic health care issues to a new level of sophistication.

The information presented in this supplement and available for HHANES represents a significant increase in our nation's ability to examine and understand the health of Hispanic Americans. It is our hope that this publication and subsequent analyses of HHANES data will provoke thought and debate and will serve as an impetus for new research on the health status and health care needs of our nation's 23 million Hispanic men, women, and children.

I. Hispanic Health and Nutrition Examination Survey: Methodological Considerations

Jane L. Delgado, PhD, Clifford L. Johnson, MSPH, Ila Roy, MSW, and Fernando M. Treviño, PhD, MPH

Abstract: The Hispanic Health and Nutrition Examination Survey (HHANES) was the first special population survey undertaken by the National Center for Health Statistics. The HHANES was designed to assess the health and nutritional status and needs of Mexican Americans, mainland Puerto Ricans and Cuban Americans. Data were collected using five data collection techniques: direct physical examinations, diagnostic testing, anthropometry, laboratory analyses, and interviews. Unlike other surveys conducted by the National Center for Health Statistics, the HHANES was not designed as a national survey. The HHANES was a survey of three Hispanic subgroups of the population in selected areas of the United States with a survey universe that included approximately 76 percent of the 1980 Hispanic-origin population in the United States. This article discusses statistical issues that should be addressed by researchers when analyzing HHANES data. Specifically, analysts need to account for the complex sample design, nonresponse bias, potential non-coverage bias, and the regional nature of the HHANES sample. [*Am J Public Health* 1990; 80(Suppl):6–10.]

Introduction

HHANES is the largest and most comprehensive Hispanic health survey ever carried out in the United States. It collected a wide spectrum of socioeconomic, health and demographic data; administered physical and dental examinations; took diagnostic specimens and conducted specialized tests, producing one of the most complete and unique Hispanic health data bases available to date.

History

The roots of the survey can be traced to 1977 when the National Academy of Public Administration was contracted to evaluate the National Health and Nutrition Examination Survey (NHANES). An expert panel, formed to assess NHANES utility in addressing nutrition-related public health issues, recommended that the National Center for Health Statistics (NCHS), the agency of the Public Health Service commissioned to carry out NHANES, should consider studies of the health and nutrition status of major subpopulation groups which could yield estimates comparable to those of the general US population.[1] The Hispanic population was subsequently selected as the special population group to be surveyed due to its size and the lack of available health status data. This study enables researchers to compare results available for the general population.

Planning for the survey began in 1979 with actual data collection occurring over a two-year period (1982–84) in three regions of the United States. HHANES surveyed Hispanics from the three major Hispanic subgroups as indicated by the 1980 Census: Mexican Americans, Puerto Ricans and Cuban Americans. Analysis of HHANES data began in earnest in 1986 when agreements were entered into with the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO) to establish the Hispanic Health Research Consortium (HHRC).

Design

HHANES became the first special population survey undertaken by the National Center for Health Statistics to assess the health and nutritional status and needs of Hispanics and to investigate the access to services by this population. HHANES was designed to focus on certain selected chronic conditions rather than to provide a comprehensive picture of health status or total need for care.[2] It was also intended to provide baseline health and nutritional information for Hispanics comparable to other surveys conducted by NCHS, particularly the Second National Health and Nutrition Examination Survey (NHANES II).[3]

The stated goals of HHANES were: to conduct a study of the health and nutritional status of the Hispanic population; to produce information useful for public health planners and researchers; and to stimulate further research and investigations on Hispanic health issues. The types of information that health examination surveys contribute are related to specific conditions or measures and include: total prevalence of a condition or characteristic, descriptive or normative information, and relationships between health variables and demographic factors. HHANES was designed to enable the study of all of these aspects of health.

The major chronic conditions studied by HHANES were: diabetes, hypertension, heart disease, gallstones, dental disease, otitis media and hearing problems, kidney disease, liver function, and depression. In addition, it surveyed the prevalence of immunization, alcohol consumption, cigarette consumption, and drug abuse in the population. HHANES also had as a major focus nutritional status, nutrition-related conditions (iron status and anemia, Vitamin A levels), and food consumption patterns as related to overweight, diabetes, alcohol consumption, dental health, and digestive diseases. Environmental exposure was a final aspect of the survey that measured exposure by the sample population to lead and selected pesticides.

Apart from these medical issues, questionnaires included numerous demographic and economic items. Income assistance, insurance coverage, health services use and satisfaction, acculturation, and assessment of health (both self-assessment and physician assessment) are examples of information collected on the various questionnaires for each sample person.

The Acculturation Scale

Many of these subjects are critical factors in the analyses of HHANES data, but pose special problems of their own. For example, the complex nature of acculturation makes it difficult to sort out this factor as a mediator of health problems. The eight variable acculturation scale used in the HHANES was modified from a 20-item scale developed for

Note: Author affiliations are listed elsewhere under CONTRIBUTORS.

and validated with a Mexican origin population.[4] It was not designed to assess acculturation levels of Puerto Ricans or Cuban Americans. The eight item HHANES acculturation scale assessed language ability, self-identification, parents' ethnic identification and generation in the US. Sample persons were asked: 1) what language do you speak? 2) What language do you prefer? 3) Can you read Spanish? English? Which do you read better? 4) Can you write Spanish? English? Which do you write better? 5) How do you identify yourself? 6) What ethnic identification does/did your mother use? 7) What ethnic identification does/did your father use? and 8) Where were you born? Your mother? Your father? Each of the first seven variables is scaled from 1 to 5, where 1 represents the least acculturated category and 5 represents the most acculturated category. Variable 8 (birthplace) cannot be scaled from 1 to 5, as it was in the original scale, because of gaps in the data collected in the HHANES. In the original scale developed by Cuellar, *et al*, a first generation American was scored as a "1" (born in Mexico) and a fifth generation person was scored as a "5". The HHANES did not collect information regarding grandparents' birthplace, thus persons could only be classified as being first, second, and third or higher generation Americans. Persons who were not born in Mexico and whose parents were also not born in Mexico were coded as a "4" (third or higher generation). Nonetheless, the detailed nature of the instruments developed and administered by the HHANES has the great potential to provide a uniquely rich picture of various aspects of illness, health, and health service use (as well as barriers) in the Hispanic population.

The Target Population

It is important to note that HHANES was not designed as a national Hispanic survey; therefore, no national estimates for Hispanics can be drawn based on HHANES findings. The major difference between HHANES and previous NHANES surveys is that HHANES was a survey of three Hispanic subgroups of the population in selected areas of the United States rather than a national probability sample. Even though HHANES was not designed to be representative of all Hispanics residing in the United States, the survey universe included approximately 76 percent of the 1980 Hispanic-origin population in the United States. The three Hispanic subgroups and the area covered were: Mexican Americans residing in five southwestern states (Arizona, California, Colorado, New Mexico and Texas); Cuban-Americans residing in Dade County, Florida; and Puerto Ricans residing in the New York City metropolitan area including parts of New York, New Jersey, and Connecticut.

The target population for HHANES ideally would have been all households in the United States with at least one member of Hispanic origin. However, there are many states and counties with very small numbers or proportions of Hispanic persons. Therefore, HHANES was restricted to those areas of the country described above in order to permit an efficient operation of the survey from the standpoints of cost and logistics. Even within the areas defined for the survey, there were certain counties excluded from the survey design for the same reasons. This may result in some small bias due to noncoverage. The sample weights created for analysis and estimation purposes attempt to take into account this issue of noncoverage.

Sampling and Respondent Selection

Survey results can be generalized to these subgroups and geographic areas. The design included identification of three universes: a Mexican-origin universe made up of 193 primary sampling units (PSUs) in five Southwestern States (Texas, Colorado, New Mexico, Arizona and California); a Cuban-origin universe consisting of one PSU (Dade County, Florida); and a Puerto Rican-origin universe consisting of 16 PSUs from New York, New Jersey, and Connecticut. The PSUs were stratified to group similar counties and one was selected from each stratum. Finally, segments and households were selected from each PSU.

Within each PSU, block areas with less than a minimum number of eligible Hispanics were excluded due to the costs of interviewing ineligible households. This exclusion should be considered during interpretation of the results. Households which had at least one Hispanic member (for example, a Mexican American in the Southwest) were eligible to participate; therefore it should be noted that a small percent of non-Hispanics are included in the overall sample.

Selected households were screened to identify eligible Hispanic families and to select sample persons from these families to be interviewed and examined. Eligibility for the survey was determined by the family unit. A family was considered to be eligible if at least one family member's reported national origin or ancestry met the criteria for eligibility appropriate to the survey location. In cases where multiple origins were reported for the same person on different questionnaires in the survey, the person was considered eligible if any one of the reported origins met these criteria.

If a family was eligible for the survey, then every member of that family was eligible to be selected for the interview and examination procedures. Therefore, some non-Hispanic persons residing in Hispanic households and some Hispanic persons not meeting the above criteria were selected for the survey and examined. Thus, analysis of HHANES data can be done in one of two ways. If all sample persons are included, then the analysis is of Hispanic households (which may include non-Hispanic individuals). If only sample persons meeting the eligibility criteria are included, then the analysis is of Mexican Americans, Cuban Americans, or Puerto Ricans, respectively.

Data Collection

HHANES relied on five data collection techniques: direct physical examinations, diagnostic testing, anthropometry (body measurements), laboratory analyses, and interviews. Depending on the nature of the interviews, some were administered in the household and others were administered in private within a mobile examination center. All examinations and testing were performed in the mobile examination center located in the community.

Due to the survey's modus operandi, attrition occurred both at the in-house interviews and at a later examination in the mobile trailer. The attrition of sample persons to the health examination occurred for a variety of reasons, e.g. had undergone a recent examination, fear of having an examination, lack of time, etc. Therefore, there are interview data on a larger sample than examination data.

Oral glucose tolerance tests and an ultrasound examination of the gall bladder were administered to a half-sample of the adult population; these people were asked to fast overnight and were examined in the morning sessions.

Caution should be exercised when utilizing data from certain specialized examinations. Due to the intrusive and demanding nature of the tests, or special requirements placed to ensure accurate testing, a low response rate resulted, particularly in the case of the glucose tolerance test.

Virtually all interview staff involved in the survey were bilingual; most were also bicultural.

Response Rates

NCHS has estimated that the HHANES survey represented approximately 76 percent of the total 1980 US Hispanic civilian, noninstitutionalized population aged 6 months through 74 years. Table 1 shows the sample sizes and response rates for each of the three survey areas in HHANES. The results are presented for both the total sample and the specific origin sample as explained previously.

Statistical Guidelines

Each of the authors of the articles in this supplement was provided with detailed statistical guidelines. Because the Health and Nutrition Examination Surveys have used a complex survey design rather than a simple random sample design, standard statistical methods may not be appropriate for data analysis. Guidelines for NHANES data analysis which produce the appropriate covariance structure and population estimates have been described elsewhere, and will only be summarized here.[2,5] Sample weights must be used to produce correct population estimates since each sample person does not have an equal probability of selection. The weights incorporate the selection probabilities, and adjustments for post-stratification (in the Mexican American sample only), noncoverage and nonresponse. In addition to the sample weights, the strata and the primary sampling units from the sample design are needed to estimate the sample variances and to test for statistical significance. In general, sampling variances will be underestimated if calculated without incorporating the complex sample design. (*Note:* the complex sample estimate of sampling variance includes variability due to measurement error).

The effect of the complex sample design on variance estimates is reflected by the design effect, which is the ratio of the variance of a statistic from a complex sample to the variance of the same statistic from a simple random sample of the same size.[2] A design effect of one indicates the equality of the simple random sample variance and the complex sample variance.

TABLE 1—Sample Size and Response Rates by Survey Area and Specified Hispanic Origin: Hispanic Health and Nutrition Examination Survey, 1982–84

Survey Area and Hispanic Origin	Sample Size	Interviewed		Examined	
		No.	Percent	No.	Percent
Southwest area					
All Persons	9,894	8,554	86.5	7,462	75.4
Mexican American	9,455	8,222	87.0	7,197	76.1
Dade County, Florida area					
All Persons	2,244	1,766	78.7	1,357	60.5
Cuban	2,125	1,677	78.9	1,291	60.8
New York City area					
All Persons	3,786	3,369	89.0	2,834	74.9
Puerto Rican	3,525	3,137	89.0	2,645	75.0

However, design effects in NHANES I and II were rarely one, and the magnitude of the design effects was highly variable. Although preliminary analyses may be performed on unweighted data with standard statistical packages that assume simple random sampling, final analyses should be done on weighted data using special computer programs that use a balanced half-sample replication methods (e.g. SESUDAAN, SURREGR) which incorporate the complex sample design.[6,7]

The complex survey design with effects greater than 1 also increase the minimum sample size needed for calculation of reliable estimates of statistical parameters. The sample size requirements were calculated assuming an average design effect of 1.5. The approach was also used in the initial analyses of the HHANES data, because HHANES also used a complex sample design. However, analyses performed during data editing revealed a number of unexpectedly large (>7.5) or small (<.8) design effects.[8] The unstable variance estimates did not show a consistent pattern, nor were they alleviated by using different methods of estimating variances, stratifying, or incorporating the third level of sampling. In general, then, calculating point estimates of sample variances by using the special computer programs described earlier cannot be recommended. An interim recommendation to use average design effects to correct variances based on the assumption of simple random sampling was made for HHANES data analysis. This is not the only approach that could be used to deal with this issue. It is, however, a relatively simple and practical solution. The impact of using this approach for various types of analyses is discussed in following chapters.

Average design effects have since been calculated for many analytic variables for the three Hispanic subgroups. In general, the average design effects for the Mexican American and Puerto Rican subgroups tend to average 1.5, while those for the Cuban subgroup tend to be about 1. Thus, in developing preliminary guidelines for analysis and presentation of HHANES data, these differences in design should be considered.

Criteria for Presentation of Data

Using the information described above about the effects of the HHANES complex survey design, the following guidelines were developed for the reporting of means and percents for the HHANES data:

- If the sample size in an analytic cell is less than 25, the mean or percent should not be reported;
- If the sample size is 25–44, the mean or percent should be reported with an asterisk beside it to indicate that the statistic does not meet a minimum reliability standard;
- If the sample size is 45 or more, the mean or percent is presented without caveat.

Exceptions to these guidelines are possible in selected instances in order to more completely present a series of findings, as long as the appropriate caveats are clearly indicated.

Multivariate Analyses

Multivariate analyses should be performed in three stages as recommended by Landis, *et al*,[5] and Kovar.[8] The first stage involves running the multivariate analyses without regard to the weights or complex sampling design. The second stage consists of running the same analyses incorporating the sample weights. The third and final stage involves running the same analyses incorporating the sample weights and the complex survey design.

The second and third stages of analyses can use a transformation or "Standardization" of the statistical weight variable to arrive at unbiased test statistics. To normalize the weights to the actual sample size of the analytic sample the following equation is used:

> Normal Weight per sample person = (individual weight) * (actual sample size of analytic sample/the sum of the weights of the analytic sample).

Analysts should use software packages or procedures in stage three analyses that incorporate the complex survey design (e.g. SURREGR and SUPER CARP).[7,9] If this is not possible, other standard software packages or procedures (e.g. SAS PRICER) can be used.[10] In this latter situation, using the normalized weights and exercising caution in interpreting test statistics is essential. For example, analysts need to consider whether a significant t-statistic for a Beta coefficient would remain significant with a design effect of 2.

This can be accomplished by multiplying the denominator of the t-statistic by the square root of 2. If the t-statistic would remain significant with a survey design effect of two (or even higher), then the analyst could feel fairly comfortable with the result. However, if the result would change with a design effect somewhere between one and two, then the interpretation of the finding should be qualified and supported by other findings in the literature.

Considerations of reliability of test statistics also require the stage three analyses incorporate some allowance for the variability as well as the size of the design effect. Analysts were advised to limit the number of independent variables per analysis to no more than the number of degrees of freedom for a given analysis, usually defined as the number of PSUs minus the number of strata (see B. V. Shah's discussion in the documentation for SURREGR). For example, separate regression analyses for NHANES II Whites and Blacks should include no more than 32 and 16 variables, respectively; and analyses of Mexican Americans, Cuban Americans, and Puerto Ricans should include no more than eight variables. For the same reason, (i.e. considerations of reliability), the forward approach is preferred to the backward approach in variable selection for regression analyses.

In summary, multivariate analyses should always be undertaken with a purpose in mind and caution in interpretation of the results. The complex NHANES and HHANES surveys with relatively small numbers of PSUs, and, in some cases, sample sizes, require the analyst to exercise good judgment and to realize that some of their analyses would result in more hypothesis-generating than answering.

Comparing NHANES and HHANES Results

The average design effect approach can be used to calculate complex sample variances for both NHANES data and HHANES data as described previously. This results in one common approach being used to handle the complex sample design for both surveys. A second approach involves calculating individual complex variance estimates from the appropriate software programs mentioned previously for all races and for Whites from NHANES I or NHANES II. These are combined with average design effect variance estimates for Blacks from NHANES I or NHANES II and Mexican Americans, Cuban Americans, and Puerto Ricans from HHANES. This mixed approach is much more difficult to explain to the reader, but is an acceptable alternative. Regardless of the approach selected, a t-statistic should be used in any statistical testing of differences between the various population groups.

Conclusions

It is important, apart from its specific scope, to be aware of the limitations of HHANES data in terms of the manner in which the sample design and response rates affect analyses and interpretation of the findings. The interpretation of results should be made with the following factors in mind:

- *HHANES does not have a simple random sample design.* Only weighted estimates are considered accurate in reflecting the sub-population to which the sample person participating in HHANES belongs. It is necessary, during analysis, to incorporate the sample weights provided by NCHS on each data tape. Because of the complex sample design and the ratio adjustments used to produce the sample weights, commonly used methods of point and variance estimation and hypothesis testing which assume simple random sampling may give misleading results.
- *Nonresponse bias in HHANES.* There exists the potential for three levels of nonresponse: household interview nonresponse, examination nonresponse, and item nonresponse. The potential effect of any nonresponse bias is greater when response rates are low. Therefore, intense efforts were undertaken during HHANES to develop and implement procedures and inducements that would reduce all types of nonresponse and thereby reduce the potential for bias in the survey estimates. Despite these efforts, a number of sample persons did not participate in the survey (see Table I). Therefore, it is important that any analysis of HHANES data include some assessment of the possible impact of nonresponse bias on the results.
- *Potential non-coverage bias in HHANES sample.* Due to the exclusion of areas with few Hispanic residents, there is a potential non-coverage bias in the HHANES sample that should be considered when interpreting results.
- *HHANES was not designed as a national Hispanic survey.* No national estimates for Hispanics can be drawn based on HHANES findings. Neither can the data for the three Hispanic subgroups be combined to produce a single estimate for the entire Hispanic population. Only regional estimates for the three subpopulations included are possible.

Due to its complex nature, it is important to be thoroughly familiar with the HHANES data base for its applicability to research areas under consideration and for analytical procedures suggested. This is facilitated by ample documentation now available on the subject as well as the documentation accompanying each data tape. When properly used, the HHANES data base constitutes an invaluable and unique resource for studying the health and nutritional status of the Hispanic population.

II. Acculturation, Access to Care, and Use of Preventive Services by Hispanics: Findings from HHANES 1982–84

JULIA M. SOLIS, PHD, GARY MARKS, PHD, MELINDA GARCIA, PHD, AND DAVID SHELTON, MS

Abstract: Use of preventive health services (physical, dental, and eye examinations, Pap smear and breast examinations) among Mexican American, Cuban American, and Puerto Rican adults (ages 20–74) was investigated with data from the HHANES. Analyses focused on the relative importance of two predictors of recency of screening: access to services (health insurance coverage, having a routine place for care, type of facility used, having a regular provider, travel time) and acculturation (spoken and written language, ethnic identification). Regression analyses controlling for age, education, and income indicated that utilization of the preventive services was predicted more strongly by access to care than by acculturation. For each Hispanic group, having a routine place for health care, health insurance coverage, and a regular provider were each significantly associated with greater recency of screening. Type of facility used and travel time produced less consistent effects. These results replicate past studies that have demonstrated the important link between institutional access and use of health services. Of the acculturation variables, language but not ethnic identification (which was measured only for the Mexican Americans) predicted use. This latter finding, which has been demonstrated in other studies as well, suggests that the effect of language on screening practices should not be interpreted as a cultural factor, but as an access factor, i.e. use of English favors access to services. [*Am J Public Health* 1990; 80 (Suppl):11–19.]

Introduction

Despite the steady improvement in the health status of Americans generally, Hispanics in the United States continue to be at greater risk for health problems.[1] This risk may stem, in part, from underutilization of screening services for the prevention and early detection of disease. Mexican Americans, for example, are less likely than non-Hispanic Whites to use such services as routine medical check-ups, dental and eye examinations, prenatal care, and family planning.[2–6]

Two general hypotheses can be invoked to account for Hispanics' underutilization of preventive health services. One hypothesis argues that level of acculturation of Hispanics influences their utilization patterns.[7–9] As discussed by Keefe,[10] acculturation is the process of change that occurs as a result of continuous contact between cultural groups. Although such a broad definition does not specify the types, degree, or direction of change expected, studies have largely presumed that Hispanics who have adopted the behavioral practices and values of the dominant society are more likely to utilize health services.[8]

Indirect support for this view comes from studies indicating that Mexican Americans used preventive services less than the general population,[3–5,11] even after controlling for sociodemographics and health insurance coverage. These studies, however, did not measure acculturation directly; thus they can only presume that the differences are due to cultural factors. Other studies have measured acculturation with multidimensional scales or with measures of language preference. Some suggest an effect of acculturation on utilization of health services,[6,12–14] whereas others fail to find an effect.[15–17] Despite these inconsistent results, a trend is apparent. Those studies that defined acculturation as language preference found that use of English related to use of oral contraceptives[13] and to fewer perceived barriers to medical care.[14] Further, a recent study[15] that examined several dimensions of acculturation (language, country of origin, contact with homeland, parental expectations of their children) found that language was the only dimension that predicted use of breast cancer screening among elderly Hispanic women; those who used English went for screening more recently. Taken together, these studies suggest that aspects of language may be especially important to our understanding of Hispanics' use of medical screening programs.

A second hypothesis attributes use of preventive health services to access to care. Access can be defined in terms of factors that influence the ease with which medical care can be obtained.[5] Such factors include the availability of health insurance, having a routine place of care and a regular provider, type of health care facility used and its proximity to residence.[5]

Compared to the general population, Hispanics are less likely to have health insurance coverage and less likely to have a routine place for obtaining health services.[5,18–21] This reflects their low income, low education, and employment in positions that do not provide insurance benefits.[4,5,22,23] Because of these barriers, they are more likely to rely on public health facilities, hospital outpatient clinics, and emergency rooms,[20,21,24,25] and are not likely to see a particular physician on an ongoing basis.[20] The "working poor" represent a segment of the Hispanic population that is especially vulnerable to access barriers in that they are neither able to afford the rising costs of medical services nor eligible for assistance through governmental programs.[21,26]

The present study provided a systematic examination of acculturation and access to care as factors influencing use of preventive health services by Hispanics. Unlike prior research on Hispanic health which has usually sampled only Mexican Americans, we examined three groups of Hispanics: Mexican Americans, Cuban Americans, and Puerto Ricans. Further, we measured use of an array of preventive services (e.g., routine physical, dental, and eye examinations, Pap smear, and breast examination).

Method

Sample

The data for our analyses were collected in the Hispanic Health and Nutrition Examination Survey (HHANES) conducted by the National Center for Health Statistics (NCHS) from 1982 through 1984. This survey sampled Mexican Americans from five southwestern states (California, Arizona, New Mexico, Texas, and Colorado), Cuban Americans from Dade County (Miami) Florida, and Puerto Ricans from

---

NOTES: Author affiliations are listed elsewhere under CONTRIBUTORS.

the New York City area. For detailed information about the complex sampling design see the methodological paper[27] at the beginning of this supplement and NCHS plan and operation of HHANES.[28]

Selected sociodemographic information, as well as analytic sample sizes, are presented in Table 1. Analyses were restricted to eligible Hispanic sample persons between the ages of 20 and 74 who provided data on each variable used in the study. There were few cases of missing data. Of the total number of Mexican Americans, Cuban Americans, and Puerto Ricans (ages 20–74) sampled, 89 percent, 92 percent, and 93 percent, respectively, were included in the analytic samples.

Measures

Preventive Behavior—Utilization of preventive services was measured by responses to queries on seven service-related behaviors. The first item listed below was considered indicative of a person's tendency to *plan* his/her use of services, while the other six measures concerned recency of use of specific types of medical examinations.

- Individuals were asked whether or not they had made an appointment for their last visit to a health care setting.
- "About how long has it been since you had a *routine* physical examination, that is, not for a particular illness but for a general check-up?" (Responses were coded on a five-point scale ranging from "never" [1] to "less than one year ago" [5].)
- "About how long has it been since you last saw a dentist or dental hygienist for dental care?" (Responses were coded from "never" [1] to "six months ago or less" [6].)
- "When was the last time you had your vision tested?" ("Never" [1] to "six months ago or less" [6].)
- "About how long has it been since you last had your blood pressure taken?" ("Never" [1] to "six months ago or less" [4].)
- "About how long has it been since you had a Pap smear test for cancer?" ("Never" [1] to "less than one year ago" [8], females only.)
- "About how long has it been since you had your breasts examined by a doctor or other health professional?" ("Never" [1] to "less than one year ago" [8], females only.)

Preliminary analyses revealed that, for each sample, responses to these seven measures were positively correlated (r .11 to .74). Thus, we created a preventive index for each respondent separately for each sample. Each of the seven items was standardized to a mean of zero and a variance of one to give each equal weight. For the females, the seven standardized items were averaged to form the index; for the males, each of the five relevant standardized items was averaged to form the index. We should note that the HHANES did not examine use of health services over time; thus recency of use of the aforementioned services was the best indicator of regularity of use.

Acculturation– This construct was assessed with eight items pertaining to spoken and written language and to ethnic identification. The items represent a subset of the 20-item "Acculturation Rating Scale for Mexican Americans" developed by Cuellar, *et al.*[29]

1. What language do you speak?
2. What language do you prefer?
3. What language do you read better?
4. What language do you write better?

These four language measures, as well as the four ethnic measures below, were coded so that higher scores reflected a stronger English language/American orientation. Items 1–4 ranged from "Spanish only" [1], to the midpoint "Spanish

and English equally" [3], to "English only" [5]. The four remaining items measured ethnic identification:

5. What ethnic identification do you use?
6. What ethnic identification does/did your mother use?
7. What ethnic identification does/did your father use?
8. Where was the birthplace of yourself, your mother, your father?

For the Mexican American sample, the response codes for items 5–7 ranged from "Mexican" [1], to "Mexican American" [3], to "Anglo or other" [5]. For the Cuban Americans and Puerto Ricans, responses to items 5–7 had highly restricted variance; almost all of the Cuban Americans (and their parents) identified themselves as "Cuban"; the same situation occurred for the Puerto Ricans. Thus, these items could not be used meaningfully for these two groups. Item 8 was coded to establish generation. The scale ranged from "first generation (respondent born in country of origin)" [1] to "third or higher generation (respondent and both parents born in United States)" [4]. This item could not be used for the Cuban Americans and Puerto Ricans because of restricted variance; 97.3 percent of the Cuban Americans (ages 20–74) and 80 percent of the Puerto Ricans (ages 20–74) were first generation. Thus, for these two samples, only the four language items were used to assess acculturation. For the Mexican Americans, all eight items were used.

We constructed separate indices of acculturation for each respondent. Because we were interested in analyzing the effects of the different dimensions of acculturation and not just acculturation in general, we performed a factor analysis with the Mexican American data. It suggested that the items could be meaningfully grouped into one of three factors: (a) language preferred and spoken (items 1 and 2); (b) language written and read (items 3 and 4); and (c) ethnic identification (items 5–8). Each Mexican American respondent was assigned a score on each of these three dimensions by first standardizing the items that grouped together on the particular dimension and then averaging the items. Additionally, an overall score was created by averaging all eight items. For the Cuban Americans and Puerto Ricans separately, items 1 and 2 were standardized and then averaged to form a prefer/speak score, and items 3 and 4 were combined in similar fashion to form a read/write score. An overall score for the Cuban Americans and Puerto Ricans was calculated by averaging the four language items.

Access to health care—Five indicators of accessibility of health services were examined.

1. Health insurance, including private as well as public and federal/military assistance (e.g., Medicare, Medicaid, other public assistance, CHAMPUS*, other military programs). Any form of coverage was coded 1; no coverage was coded 0.
2. Whether or not the respondent had a routine place he or she used for health care (yes = 1, no = 0).
3. Type of health care facility used (private clinic, doctor's office, health maintenance organization, or prepaid group [4]; community clinics [3]; hospital outpatient clinic [2]; hospital emergency room [1]). The distribution of response across these categories was somewhat skewed (see Table 3); thus, for the regression analyses categories 3 and 4 were combined and assigned a code of 2, and categories 1 and 2 were combined and assigned a code of 1.
4. Whether or not the respondent usually sees a particular provider at the facility (yes = 1, no = 0).
5. Distance between residence and facility used (less than 10 minutes [3]; between 10 and 20 minutes [2]; over 20 minutes [1]).

An overall access score was constructed by standardizing and then averaging the five measures. In addition, for some analyses the individual measures of access were examined separately.

Data Analysis

All analyses were performed separately for each of the three samples, and separately for men and women applying normalized sample weights (examination weights).[27] We examined the weighted prevalence of preventive behavior and the weighted prevalence of access to services. Associations among variables were examined with weighted Pearson correlations. Our primary analyses of the effects of acculturation and access on recency of utilization were performed with multiple regression. Several regression models were tested, using as predictors the overall acculturation and overall access scores, and in different models using the individual components of these overall scores. Sociodemographic factors (age, education, income) were also included in the equation. Prior to conducting these tests, a statistical program (SESUDAAN)[30] was run to calculate the average design effect for each predictor variable. This average design effect was used to conservatively adjust the standard error of a regression coefficient generated by a weighted ordinary least-squares analysis. We should emphasize that, although certain variables were examined as "predictors," the HHANES is a cross-sectional design; thus, it does not provide evidence regarding cause and effect.

Results

Prevalence of Health Service Utilization

For each sample, recent use of the preventive health services was more prevalent among females than males (Table 2). Further, except for Pap smear and breast examination, recent use was higher among Cuban Americans and Puerto Ricans than among Mexican Americans. For example, less than 50 percent of the Mexican Americans reported that they had a routine physical examination within the last two years, and approximately 20 percent of the Mexican Americans reported that they never had a regular check-up from a physician. A similar pattern occurred for eye and dental examinations; recency of the female examinations was comparable among the samples.

Access to Health Services

The data suggest an association between access to care and utilization of health services. As seen in Table 3, a greater percentage of women than men reported that they had a routine place for health care and that they usually saw a particular provider at the facility. This gender difference in access parallels the gender differences in utilization described above. Second, fewer Mexican Americans (compared to the other two groups) had some form of health insurance coverage (Table 3) which may partially explain their low rate of screening. Finally, consistent with prior research,[31] a substantially larger percentage of Puerto Ricans compared to

Mexican Americans and Cuban Americans used hospital outpatient clinics and hospital emergency rooms as their usual source of health care (Table 3).

Access was correlated with sociodemographic factors. For Mexican American and Cuban American men and women, the overall access score correlated positively with education, annual income, and age (r .10 to .25). The correlation between health insurance coverage and income was especially strong (r .24 to .37). A similar pattern of results was found for Puerto Ricans, but the correlations were not as strong.

Regression Analyses

Overall Effects—The first set of multiple regression analyses used the overall acculturation score, the overall access score, and sociodemographic factors (education, income, age) as predictors of the preventive service use index. The predictors were entered into the equation simultaneously; thus, the effect of each variable was assessed after controlling for the effects of each of the other variables in the equation. As seen in Table 4, the R^2 from each analysis indicated that the array of predictors accounted for more

variance in the men's preventive behavior than the women's. With respect to individual effects, access to health services was a uniformly strong predictor in each sample. Acculturation, however, was an important predictor only for Mexican American and Cuban American men. The regression coefficients for the sociodemographic variables were small, but the pattern indicated that increased education, increased income, and older age were associated with greater recency in utilization of the health services.

Specific Effects of Acculturation—Additional regression analyses were performed to examine the effects of the individual components of the overall acculturation score (spoken language, written language, and ethnic identification). Because these three components were moderately to highly correlated (*r* .53 to .81), analyzing the three together in a simultaneous model could generate misleading results due to the multicollinearity among the variables. Thus, in addition to testing a simultaneous model, we tested three additional models in which the acculturation measures were analyzed separately. The effects of ethnic identification could be examined only for the Mexican Americans. All of the analyses controlled for age, income, and education.

As seen in Table 5, for Mexican American men and women, Model 1 (all three acculturation variables analyzed together) indicated that only spoken language was significant. That is, preferring to speak English was associated with greater recency in utilization of the services. Models 2, 3, and 4 (which analyzed the three acculturation variables separately) yielded results consistent with the first model. Although spoken language (Model 2) and written language (Model 3) each were predictors, spoken language was the stronger predictor. Ethnic identification was not a predictor in either the simultaneous or individual model (Model 4).

The findings for Cuban Americans and Puerto Ricans were not as clear. For Cuban American men, written language produced stronger effects than spoken language, and neither language dimension produced appreciable effects for Cuban American women or for Puerto Rican men and women.

Specific Effects of Access—Not surprisingly, some of the access variables were correlated. For each sample, having a particular provider was correlated with using HMOs or private clinics (*r* .28 to .48) and with having a routine place for health care (*r* .34 to .60). The correlations among the other access variables were much smaller.

A series of regression analyses were performed that tested simultaneous as well as individual models for the specific access variables. The simultaneous model (Model 1) indicated that, for each sample, having a routine place for health care was generally the strongest predictor of recency in utilization (see Table 6). Comparison of the individual models also reveals that having a routine place for care produced the strongest effects (Model 3). The findings for health insurance were strong in both the simultaneous and the individual model (Model 2), and having a particular provider was a predictor in the individual model (Model 5). The results for the other measures of access were less consistent. Type of health care facility used most often was a predictor only for the men of each sample and only when this variable was the sole access variable in the equation (Model 4). Finally, distance from facility was predictive of utilization only for Puerto Ricans (Model 6); as distance decreased, recency of screening increased.

Discussion

Our analyses unveiled interesting differences in preventive service-related behaviors among the three Hispanic groups. Mexican Americans used such services less recently than the other two groups, except in the case of female examinations. Previous research has also shown that Mexican Americans are less likely than non-Hispanic Whites and Blacks to visit a physician or a dentist, or to be admitted to a hospital.[32] In part, this can be explained by the fact that Mexican Americans are less likely than others to have health insurance as demonstrated in the present and other studies.[33]

There are several reasons for the higher prevalence of health insurance coverage among Cuban Americans and Puerto Ricans. Cuban Americans compared to Mexican Americans are more likely to have private insurance coverage as a result of higher incomes and/or greater availability of health insurance as an employee benefit.[33] Puerto Ricans, however, are more likely than Mexican Americans to be covered by Medicaid; they have higher proportions of female-headed households eligible for Medicaid under Aid to Families with Dependent Children and are more likely to reside in states that provide greater optional coverage under Medicaid.[26,33] The higher prevalence of Medicaid coverage among Puerto Ricans may also explain their greater use of public facilities.

At the outset, we offered two hypotheses to explain the use of preventive health services by Mexican Americans, Cuban Americans, and Puerto Ricans; one emphasized the importance of acculturation and the other emphasized access

to services. Our findings clearly demonstrated that access was strongly related to utilization. In particular, having a routine place for care and having health insurance coverage produced the strongest effects. With respect to acculturation, language but not ethnic identification was the important predictor of utilization for the Mexican Americans. Language was related to utilization for the Cuban American men but not for the Cuban American women or Puerto Ricans. We are uncertain why the language effect was not found among these latter Hispanic subgroups. In the case of the Puerto Ricans, the public health facilities they tend to use (because of their high rate of Medicaid coverage) may have more Spanish-speaking providers than private clinics and hospitals so that use of the English language may not be essential to access.

Despite the differential effect of language among the three Hispanic groups, language was clearly associated with recency of screening. A prior study obtained similar results.[15] Of four dimensions of acculturation (language, country of origin, contact with homeland, parental expectations of children) only language was significantly associated with use of screening examinations (e.g., physician breast examination, breast self-examination). Further, as discussed earlier, several studies have found that service utilization rates were higher among non-Hispanic Whites than Hispanics after controlling for sociodemographic factors and health insurance coverage.[3–5,11] Although this difference has been attributed to cultural factors in the broad sense, the present data suggest that the results were probably due to specific language differences between the groups.

What interpretation should be placed on this language effect? Traditionally, the effect of language has been viewed as an indicator of the importance of cultural factors in health service utilization. If cultural factors were important, one would expect to find strong effects of language as well as significant effects of the psychological and social dimensions of acculturation. These latter dimensions, however, have not been shown to be associated with screening behavior. This causes us to question the usefulness of a broad cultural interpretation of the language effect. Our preferred view is that language represents an access factor. Although language preference can be viewed as a measure of cultural integration, it also can be seen as an indicator of functional integration.[34] From this latter perspective, ability to speak English increases the extent to which Hispanics can effectively attain institutional access. This view is consistent with several prior papers that have discussed language as a potential barrier to health service delivery.[7–9] In sum, regardless of one's level of acculturation on psychological or social dimensions, variation in language preference seems to be a critical determinant of utilization of health services, and is best viewed in terms of accessibility.

Recommendations

The present results support several ideas discussed in the literature for increasing the use of health services by

Hispanics. Because our data indicate that Mexican Americans are the least likely of the three Hispanic groups to be recent users of preventive services, the following recommendations are particularly relevant to them.

- First, special outreach efforts need to be conducted with Hispanics who are monolingual Spanish or prefer to speak Spanish regarding the importance of medical screening for prevention of illness. Programs directed toward medical providers regarding language issues, increasing bilingual staff, and programs dealing with patient-provider interaction would also be beneficial.
- Second, the present data showed that those with a regular source of care and a particular provider (e.g., family doctor, private clinic, prepaid group) were most likely to use preventive services. Because large portions of Hispanics do not have a regular provider, it would seem important either to: (a) incorporate screening programs into the settings that are used by them, or (b) establish effective referral mechanisms to direct individuals to screening centers.
- Finally, lack of health insurance is a barrier to the use of preventive services, particularly among Mexican Americans. This suggests the need to: 1) increase the availability of low-cost or no-cost medical screening programs in low income Hispanic communities; 2) increase the availability of health insurance coverage as an employee benefit; 3) broaden the eligibility criteria for Medicaid (which in many states is re-

III. Health Risk Behaviors of Hispanics in the United States: Findings from HHANES, 1982–84

Gary Marks, PhD, Melinda Garcia, PhD, and Julia M. Solis, PhD

Abstract: With data from the Hispanic Health and Nutrition Examination Survey (HHANES), we examined several health risk behaviors (cigarette smoking, alcohol use, dietary practices, and recency of health screening) of Mexican American, Cuban American, and Puerto Rican adults (ages 20–74). For each sample, a greater percentage of men than women smoked cigarettes and used alcohol. Heavy smoking (20+ cigarettes per day) was most prevalent for Cuban American males, and heavy drinking (1.00+ oz ethanol per day) was most prevalent for Mexican American and Puerto Rican men. Acculturation correlated positively with alcohol use (particularly for females) and negatively with dietary balance (for Mexican American men and women). The Puerto Ricans' diet was less balanced than that of the other two groups. For each sample, more men than women had not had a routine physical or dental examination within the past five years; the recency of screening was lowest for Mexican American men. Screening (including Pap smear for the women) was lower for those who smoked cigarettes and for those with poor dietary practices, indicating that many Hispanics at special risk of disease underutilize preventive health services, increasing the likelihood of diagnosis at a later stage of illness. [*Am J Public Health* 1990; 80(Suppl):20–26.]

Introduction

Compared to non-Hispanic Whites in the United States, Mexican Americans underutilize preventive health services such as routine physical check-ups, dental and eye examinations, and prenatal care.[1–5] When they present with an illness, the illness frequently is at a later stage.[6,7] Consequently, Mexican Americans are at greater risk of morbidity and mortality than the general United States population.[8]

The screening behavior of persons of Mexican heritage has been shown to be affected by: *access to care*, such as having a regular family physician and health insurance coverage;[2,3,5,9] *cultural variables* such as adaptation to the practices of American society;[5,10–12] and *sociodemographic factors* such as income, education, age, and gender.[13,14] The extent to which utilization of preventive health services is influenced by attitudinal and behavioral factors, however, has received much less attention.

Attitudes about health are reflected in many behaviors. For example, those who smoke cigarettes heavily,[15–17] drink alcohol excessively,[18,19] or maintain an unbalanced and unvaried diet (e.g., high in fried meats and low in fruits, vegetables, and fiber[17,20,21]) place themselves at increased risk of specific diseases, such as cancer of the lungs, pancreas, colorectal area, and prostate,[17,20–25] and hypertension and coronary heart disease.[26,27] Ideally, individuals who engage in these "health risk-behaviors" should use screening services regularly in order to monitor their health status. We suspect, however, that (after controlling for income, education, age, and acculturation) they use those services *less* frequently than individuals who do not engage in such behaviors, based on the assumption that such behaviors are components of a constellation that emanates from a general attitude toward health promotion and disease prevention.[28] This cluster of behaviors is likely to contribute to the presence of illness and to diagnosis at a later stage.

We provide data on the prevalence of these health risk behaviors among Mexican American, Cuban American, and Puerto Rican adults, and examine the extent to which recency of screening (physical and dental examination, Pap smear) is correlated with them.

Methods

Sample

The study used data from the Hispanic Health and Nutrition Examination Survey (HHANES), conducted by the National Center for Health Statistics (NCHS) from 1982–1984. This survey sampled Mexican Americans from five southwestern states, Cuban Americans from Dade County (Miami) Florida, and Puerto Ricans from the New York City area. For detailed information about the complex sampling design see the methodological paper by Delgado, *et al*,[29] at the beginning of this supplement and the NCHS plan and operation of HHANES.[30]

Our analyses focused on adults (20–74 years of age) from each of these three samples. Table 1 presents the total sample sizes in this age range, the analytic sample sizes, and selected sample characteristics. Analyses were restricted to eligible Hispanic sample persons who provided data on each variable used in this study. Of the total number of Mexican Americans, Cuban Americans, and Puerto Ricans (20–74) sampled, 85 percent, 86 percent, and 87 percent, respectively, were included in the analytic samples.

Measures

Health Service Utilization—Recency of physical examination was measured by asking "How long has it been since you had a *routine* physical examination, that is, not for a particular illness, but for a general check up?" Responses were coded on a 5-point scale ranging from "never" [1] to "less than one year ago" [5]. Recency of dental examination was assessed by asking how long it was since they saw a dentist or dental hygienist for dental care (coded from "never" [1] to "six months ago or less" [6]). Recency of Pap smear was examined for the women ("never" [1] to "less than one year ago" [7]).

Cigarette Smoking—This behavior was measured two ways: (a) a dichotomous measure reflected whether or not the respondent was a current cigarette smoker (current smoker = 1; does not currently smoke cigarettes, cigars, or pipes = 0; the few persons who smoked cigars or pipes only were not included in the analyses); or (b) among current cigarette smokers, each was assigned a score indicating the number of cigarettes smoked per day. These two measures allowed us to examine whether the effects of smoking are due to mere

The percentages for marital status, age, income, and education were calculated with normalized sample weights (examination weights).

smoking status (smoker vs nonsmoker) or to magnitude of smoking among current smokers.

Alcohol Use—Alcohol consumption was grouped into four volume levels: (a) little or no current use (fewer than 12 drinks of beer, wine, or liquor in one's entire life or in any one year, or no current use); (b) light regular/occasional drinkers (light regular drinkers consumed an average of 0.01 to 0.21 oz of ethanol per day, occasional drinkers drank in the light ethanol range or above but did so irregularly); (c) moderate regular drinkers (an average of 0.22 to 0.99 oz of ethanol per day); and (d) heavy regular drinkers (an average of 1.00 or more oz of ethanol per day). The ethanol scale was constructed by NCHS using a conversion factor in which one oz of beer contains 0.04 oz of ethanol, one oz of wine contains 0.15 oz of ethanol, and one oz of hard liquor contains 0.45 oz of ethanol.

Diet Index—Diet was assessed with a food item and consumption frequency checklist similar to that used by others.[17,20,22,23] Respondents reported on all food items consumed in the past three months. They indicated whether they had eaten the food item daily (coded as a score of 3), weekly (2), less than once a week (1), or never (0). We constructed an overall diet index that consisted of two components. One component was the extent to which an individual's diet was balanced. Specific food items were grouped into dairy products, meats (including poultry and fish), fruits, vegetables, and grains/cereals. For each person, scores were averaged separately for each food group, and then the five subscale scores were averaged. Higher overall scores indicated a more balanced diet (i.e., frequent consumption of foods in each group). The second component consisted of a "junk food" factor, i.e., the extent to which an individual consumed items such as candy, sodas (excluding diet soda), cake, cookies, chips, sugar, etc. The overall diet index was formed by splitting the distribution of scores for dietary balance and the distribution of scores for "junk food" at their respective medians. Those high on dietary balance and low on "junk food" intake were assigned a score of 3; those high on each dimension received a score of 2; those low on each dimension received a score of 1; and those low on balance and high on "junk food" were assigned a score of 0. This index was used in the correlations and regression analyses. For descriptive purposes, we calculated the number of the five food groups from which respondents had eaten one or more food items daily, and the percentage who had eaten one or more "junk food" items daily.

Acculturation—This variable was measured with eight items pertaining to spoken and written language and to ethnic identification. The items represent a subset of the 20-item "Acculturation Rating Scale for Mexican Americans" developed by Cuellar, *et al.*[31]

1. What language do you speak?
2. What language do you prefer?
3. What language do you read better?
4. What language do you write better?

These four measures (as well as the four below) were coded so that higher scores reflected a stronger English language/American orientation. Items 1–4 ranged from "Spanish only" (1), to the midpoint "Spanish and English equally" (3), to "English only" (5). The four remaining items measured ethnic identification:

5. What ethnic identification do you use?
6. What ethnic identification does/did your mother use?
7. What ethnic identification does/did your father use?
8. Where was the birthplace of yourself, your mother, your father?

For the Mexican American sample, the response codes for items 5–7 ranged from "Mexican" (1), to "Mexican American" (3), to "Anglo or other" (5). For the Cuban Americans and Puerto Ricans, responses to items 5–7 had highly restricted variance; almost all of the Cuban Americans (and their parents) identified themselves as "Cuban"; the same situation occurred for the Puerto Ricans. Thus, these items could not be used meaningfully for these two groups. Item 8 was coded to establish generation. The scale ranged from "first generation (respondent born in country of origin)" (1) to "third or higher generation (respondent and both parents born in US)" (4). This item could not be used for the Cuban Americans and Puerto Ricans again because of restricted variance; 97.5 percent of the Cuban Americans (age 20–74) and 80.5 percent of the Puerto Ricans (age 20–74) were first generation. Thus, for these two samples, only the four language items were used to assess acculturation. These four items were standardized to a mean of zero and variance of one (to give each item equal weight) and then averaged to create a composite score for the Cuban Americans and Puerto Ricans. For the Mexican Americans, all eight items were standardized and then averaged to create the acculturation score. Demographic information on annual income, education, and age was also included in the analyses.

Data Analysis

Analyses were performed separately for each of the three samples, and separately for men and women applying normalized sample weights (examination weights).[29] We analyzed the weighted prevalence of each health risk behavior as well as the weighted Pearson correlation of these behaviors with acculturation, education, income, and age. Our primary hypothesis was examined with multiple regression analysis. The regression model for each dependent measure (i.e., utilization variable) included as predictors the three health risk behaviors, acculturation, and the three sociodemographic variables. The predictors were entered into the equation simultaneously. Prior to conducting these tests, a statistical program (SESUDAAN)[32] was run to calculate the average design effect for each predictor variable. This average design effect was used to conservatively adjust the standard error of a regression coefficient generated by a weighted ordinary least-squares analysis. We should emphasize that although certain variables were examined as "predictors," the HHANES is a cross-sectional design; thus, it does not provide evidence regarding cause and effect.

Results

Prevalence of Health Risk Behaviors

For each sample, behaviors that increase one's risk of illness and disease were more prevalent for men than women. A greater percentage of the men smoked cigarettes and drank alcohol heavily (Table 2). Heavy cigarette smoking was most prevalent for Cuban American men, and heavy drinking most prevalent for Mexican American and Puerto Rican males. Dietary balance was somewhat lower for men than women, and lower for the Puerto Ricans compared to the other two groups. Further, for each sample, more men than women had not had a physical or dental examination within the last five years. These gender differences occurred for those above, as well as for those below, the median on the acculturation index. The utilization of the health services was especially low for the Mexican American men. Table 2 also indicates that use of the preventive services was lower for the Mexican Americans than the Cuban Americans and Puerto Ricans. One explanation for this difference is that fewer Mexican Americans had some form of health insurance coverage.[5]

Correlation of Health Risk Behaviors with Acculturation and Sociodemographics

With only a few exceptions, the pattern of the correlations was similar for men and women, and for each sample (Table 3). Because of the relatively large sample sizes, many of the coefficients were statistically significant even though their absolute magnitudes were low. There were, however, several meaningful effects. The strongest associations involved acculturation, which correlated with increased alcohol consumption (particularly for the women of each sample), and with lower diet scores for the Mexican American men and women. As age increased, alcohol consumption decreased; the correlations between age and cigarette smoking and between age and diet were small. Those with more

education and higher income (especially the women) consumed a greater volume of alcohol.

Correlates of Screening

Smoking—In separate regression analyses the two cigarette smoking measures were examined as predictors of recency of screening. Only the dichotomous measure was significant, which suggests that the key factor associated with screening activity was whether or not one smokes, not necessarily the amount one smokes. As seen in Table 4, among the Mexican Americans and Cuban Americans, smokers were less recent users of the health services than were the nonsmokers. These effects are seen more concretely in Table 5, which presents the weighted prevalence of recent utilization by smoking status (not controlling for other factors). The findings were strongest for the Mexican American and Cuban American men; for these two groups, the results were consistent across levels of acculturation. The relation between smoking and screening for the Puerto Rican men and women was generally in the predicted direction, although very weak.

Diet—Dietary practices were associated with screening, especially for the Mexican American women. Among this subgroup, those with poorer diets (i.e., low in balance and high in "junk food" intake) were less recent users of the health services (Tables 4 and 5). This association was not qualified by the degree of acculturation of the Mexican American women.

An interesting pattern emerged for the diet and smoking variables for the Mexican American sample. Whereas the

[a]The "low" diet score includes individuals who received a score of 0 or 1 on the overall diet index; the "high" diet score includes persons who received a score of 2 or 3 on the overall diet index.

association between dietary behavior and screening was stronger for the women than the men, the relation between smoking and screening was stronger for the men than the women. These gender-specific associations were not as clear for the Cuban Americans or Puerto Ricans.

Alcohol—The results for alcohol consumption were mixed. Some of the regression coefficients suggested that heavier drinking tended to associate with less recent use of the health services (e.g., Mexican American men/physical examination), while other coefficients suggested the opposite. We attempted to clarify the picture by examining a subset of heavy drinkers who did not suffer from chronic illnesses (diabetes, heart disease, hypertension) that may necessitate regular visits to a physician. Analyses of this subset, however, yielded essentially the same null and mixed results. Second, among those with no chronic illnesses we compared screening rates for two extreme groups: nondrinkers versus heavy drinkers (those drinking an average of 1.00 or more oz of ethanol per day). Again, most of the results were nonsignificant. Thus, the hypothesis regarding the association between heavy drinking and infrequent use of preventive health services was not confirmed.

Acculturation and Sociodemographics—These factors did not produce strong effects. Increased acculturation tended to be associated with greater recency of screening for the Mexican Americans and Cuban Americans. Higher levels of education and higher income (primarily for the Mexican American men and women) were related to more recent use of the services, although the regression weights were small. The effects of age were minimal.

Discussion

Cigarette smoking, poor dietary practices, and excessive alcohol consumption place individuals at risk of specific disease.[20–27] Ideally, those who engage in these health risk behaviors should use preventive health services regularly in order to monitor their health status. The present study demonstrated several instances in which those at risk were screened *less* recently than those not at risk. Such underutilization increases the likelihood of diagnosis of illness at a later stage.

For each sample, risk of disease was greater for men than women. Men were more likely to be smokers, heavier smokers, and heavier alcohol users; also, their screening rates were much lower than the women's. These gender differences held across level of acculturation, which suggests that similar results would be found in non-Hispanic populations.

The gender effects may stem from sex-role norms. The strong emphasis in our society on self-reliance and independence for men may contribute to their less-than-optimal health attitudes and practices.[33] Further, these norms may influence personal beliefs about one's invulnerability to illness,[34] which may be held more strongly by Hispanic men than Hispanic women. Such beliefs are likely to impact negatively on preventive action.[35]

We found significant positive correlations between acculturation and alcohol consumption, especially for the women of each sample. These findings are consistent with the acculturation model of alcohol use,[36–38] which emphasizes normative influence on behavior. The dominant norms guiding alcohol consumption among non-Hispanic women are more liberal than the cultural norms for Hispanic women—non-Hispanic women drink more frequently and drink greater quantities of alcohol than Hispanic women in general.[36] As Hispanic women acculturate, their drinking increases because their behavior becomes more strongly influenced by the norms and practices of the dominant group. The smaller correlation between acculturation and alcohol use for Hispanic men may reflect the fact that, although the specific pattern of frequency versus quantity of alcohol consumed differs somewhat between Hispanic and non-Hispanic males,[36] the drinking norms for these two groups are fairly similar.

Health risk behaviors such as cigarette smoking and poor dietary practices were associated with less recent screening activity. In particular, for the Mexican American and Cuban American men, cigarette smoking correlated strongly with less recent utilization of routine dental and physical examinations; for the women especially the Mexican American women), poor dietary practices correlated strongly with less recent screening, including Pap smear. Because the HHANES was a cross-sectional design, we cannot conclude that cigarette smoking or poor dietary practices causes one to use screening services infrequently. Rather, the data suggest that these behaviors tend to co-occur. At the outset, we suggested that the relationships may stem from a common factor, namely one's underlying attitude toward health promotion and disease prevention. It is also quite possible, however, that some smokers may actively avoid check-ups from doctors because of their anxiety about receiving negative feedback about their health or being told by the physician to quit smoking. Alternatively, some smokers may still be unaware of the link between smoking and disease, or may discount or deny that link, and thus use screening services infrequently.[39] These possibilities are not limited to any one subpopulation. The fact that we found the same inverse association between smoking and utilization for high and low acculturated Mexican American and Cuban American men suggests that our findings would generalize to non-Hispanic White populations. We should note, however, that although the associations may hold for each of these groups, the absolute level of medical screening is lower among Hispanics.[1,3]

Finally, alcohol consumption was not strongly or consistently related to screening in any of the three samples. Unfortunately, the present data do not permit a conclusion regarding the role of this health risk behavior in screening activity. One potentially important factor, however, is a person's perception of the health effects of alcohol use, which is likely to vary considerably among individuals. For example, some people with a relatively positive attitude toward health promotion may drink moderately/heavily due to the fact that they perceive the risk of drinking to be slight. Others may perceive the risk of drinking differently. This variability may occur because, compared to the clear media message about the negative effects of smoking cigarettes, the health consequences of alcohol have not been communicated as clearly or consistently. The variable beliefs about the effects of alcohol use may have contributed to the inconsistent findings for alcohol consumption and medical screening.

IV. Health Care Utilization Barriers among Mexican Americans: Evidence from HHANES 1982–84

Antonio L. Estrada, PhD, MSPH, Fernando M. Treviño, PhD, MPH, and Laura A. Ray, MPA

Abstract: Data from the Hispanic Health and Nutrition Examination Survey (HHANES) conducted by the National Center for Health Statistics in 1982–1984 were analyzed to document the type of barriers encountered which prevented Mexican Americans from obtaining health care, the sociodemographic subgroups most vulnerable to such barriers, and to examine the combined effects of predisposing, enabling, and need characteristics on these barriers.

The findings suggest, in general, that low income groups, younger age groups, the less acculturated, those who lack health insurance coverage, those with functional limitations, and those in poorer perceived health status encounter more barriers than others, and are prevented by these barriers from obtaining health care for themselves. [*Am J Public Health* 1990; 80(Suppl):27–31.]

Introduction

Mexican Americans have been found to make less use of health care than White and Black non-Hispanics, Puerto Ricans, Cuban Americans and other Hispanics.[1,2] Previous research has identified various potential barriers which may impede Mexican Americans from obtaining medical care. These barriers include, but are not limited to, language and cultural differences, lack of transportation, geographic inaccessibility, financial constraints such as the cost of health care and limited health insurance coverage, and isolation from the mainstream culture.[3–9]

Several models have been proposed to examine the utilization of health services.[10–14] One of the most widely used models is a behavioral model developed by Andersen[14] and subsequently expanded by Andersen and Newman,[15] Aday and Andersen,[16] and Andersen, *et al.*[8] In its original formulation Andersen's model conceived of health care utilization as a consequence of three general factors: 1) predisposing characteristics such as age and gender; 2) enabling characteristics such as income and health insurance coverage; and 3) need characteristics such as health status. The components of this model were hypothesized to contribute independently to the understanding of differential utilization of health services. Need characteristics have been found to be more important in predicting utilization of health services than either predisposing or enabling characteristics.[17–19]

Mechanic,[17] Rundall,[18] and Wolinsky[19] have noted several problems with the model in its current form: the low amount of utilization variance explained by the model; the specification of the model in practice as additive, when in fact the model as stated by Andersen and colleagues suggests characteristics, over and above that explained by predisposing and enabling characteristics.

The approach taken in this paper uses a multivariate model based upon Andersen and colleagues' behavioral model of health care utilization.[7,8,14,16] This model focuses on utilization barriers using health care utilization as a control in order to examine variables related to encountering barriers and being prevented by these barriers from obtaining health care.

The over-riding rationale in the model's application to utilization barriers is that if predisposing, enabling, and need characteristics help explain the over- or underutilization of health care, these same constructs may help explain why some people encounter barriers and are thus prevented from utilizing health care services.

The purpose of the present study is three-fold: to document the type of barriers to health care reported by Mexican Americans; to determine which sociodemographic subgroups are most vulnerable to such barriers; and to examine the joint effects of predisposing, enabling, and need characteristics on the barriers to health care.

Methods

In the analyses presented in this paper, sampling weights were employed to arrive at reliable point estimates, and corrections for the clustering effect introduced by the complex sample design were accounted for when means and standard errors were computed by a method developed at the National Center for Health Statistics[20] and documented in this issue of the Journal.[21] The current analyses focus on 3,935 Mexican Americans ages 20–74 years who were eligible for inclusion based on their having self-identified themselves as either Mexican, Mexican American, or Chicano.

In keeping with Andersen's multivariate framework, the present study includes predisposing, enabling, and need characteristics. Table 1 displays each of the variables under these constructs differentiated by gender and age group as well as the percentage of persons who reported encountering barriers and the percentage of persons who reported having had a physician visit within the past year.

Dependent Variables

Persons interviewed in the Hispanic Health and Nutrition Examination Survey (HHANES) were asked if they encountered a barrier when they last attempted to utilize health care (from a list of 13 possible barriers, Table 2). If they reported encountering a barrier, they were further asked if this barrier actually prevented them from receiving health care.

The two major dependent variables of interest therefore were the extent to which respondents encountered utilization barriers and whether or not these barriers prevented them from obtaining care for themselves. Utilization of a physician within the past year was used as a control variable when each of the dependent variables was examined. Barriers which prevented care from being received were dichotomized as "prevented" and "not prevented" from obtaining health care. Utilization barriers encountered is a continuous variable derived by dividing the sum of those barriers the respondent reported encountering by the total possible number of barriers reported. Not all persons could report en-

TABLE 2—Rank Order of Specific Barrier Items, Mexican Americans (N = 3935)

Barriers Encountered Which Impeded Care	Persons Reported Encountering Barrier(s) N	Persons Reported Encountering Barrier(s) %	Persons Encountered Barrier(s) Reported Care Prevented* %
Cost of health care	706	18.0	82.3
Had to wait too long in the office or clinic	376	9.5	58.9
Had to wait too long to get an appointment	365	9.3	67.0
Would lose pay from work (applicable only to those who work)	337	8.6	72.7
The hours were inconvenient	307	7.8	70.3
Care was not available when needed	256	6.5	74.0
Did not know where to go	228	5.8	75.0
Did not have transportation	224	5.7	74.2
Had no confidence in the staff	168	4.3	62.9
Needed someone to take care of your children (applicable only to those with children)	132	4.2	78.3
Staff did not speak Spanish	155	3.9	62.8
Staff was disrespectful	109	2.8	53.2
There were no Hispanic staff members	91	2.3	65.6

*The percent reported for prevented barriers is derived from those persons who acknowledged an encountered barrier. For example, 82.3 percent of those who encountered cost as a barrier said it actually prevented them from obtaining care for themselves.

countering all 13 barriers. Persons who were employed and had children could report all 13 possible barriers. Persons who either were not employed or did not have children could only report 12 possible barriers. Persons who were unemployed and had no children could only legitimately report 11 of the possible 13 barriers on the list.

Results

Sixty-seven percent of the Mexican American sample did not report encountering any barriers while approximately 33 percent of the sample reported encountering one or more barriers when last attempting to obtain health care. Among those who reported encountering barriers to health care, 73 percent reported that the barrier(s) were serious enough to actually prevent them from obtaining health care on that occasion.

The encountered and prevented barrier items were rank-ordered by the percent of respondents who reported each item (Table 2). The five most commonly encountered barriers reflect dimensions of availability and accessibility of health care. For example, cost of health care was the most frequently encountered barrier among Mexican Americans, followed by having to wait too long at the doctor's office or clinic, waiting too long to get an appointment to be seen, inconvenient clinic or office hours, and losing income as a result of having to be away from work to obtain health care.

The five barriers which were most frequently reported as actually preventing Mexican Americans from obtaining health care were somewhat different. While cost of health care was the most frequently reported, needing someone to take care of their children while they obtained health care was the second most cited barrier which prevented them from obtaining health care, followed by not having transportation to get to the source of health care, and losing pay from work while obtaining care.

In general, relatively few Mexican Americans reported encountering barriers which reflect the cultural and linguistic aspects of health care (e.g. no Spanish-speaking staff members, no Hispanic staff members, staff being disrespectful). The data seem to suggest that cost, availability, and accessibility constraints were more important than cultural constraints as measured by the HHANES.

Bivariate Associations

Predisposing Characteristics—The relationships between selected predisposing characteristics and utilization barriers were examined so as to identify sociodemographic subgroups within the Mexican American population who were most vulnerable to encountering barriers to health care. Results revealed that Mexican Americans who are younger in age, female, less acculturated, and foreign born were more likely to be prevented from obtaining health care than others.

Enabling Characteristics—Overall, the enabling characteristics examined showed a consistent and significant association with utilization barriers. Persons with low incomes or low educational levels, Spanish-speakers, those with incomes below the poverty level, the unemployed, the uninsured, and those without a regular source of care reported utilizing health care services less frequently and were more likely to encounter barriers to obtaining health care. These variables were interrelated: e.g. the unemployed have lower incomes and probably have less insurance coverage than the employed. The predisposing and enabling characteristics suggest that a significant proportion of those who can least afford health care and who are least equipped to deal with the American health care system were prevented from using health care services.

Need Characteristics—Both need characteristics examined (perceived health status and functional impairment) were found to be positively associated with encountering barriers and thus being prevented from obtaining health care. Obviously, persons in poor health and those with functional impairments have greater opportunity to encounter barriers to care due to their greater need for care and greater utilization of health services. Nonetheless, Mexican Americans with greater health needs reported encountering more barriers.

Multivariate Analyses

To assess the combined effects of predisposing, enabling, and need characteristics, separate multivariate analyses were performed with utilization barriers encountered and prevented as the dependent variables, respectively, controlling for time since last physician visit. All independent variables were entered simultaneously into each multivariate model. Therefore, the coefficients reported in Tables 3 an 4 estimate the relationship of each independent variable on the dependent variable, while simultaneously taking into account all other independent variables.

The control variable, time since last physician utilization, was dichotomized as "0" meaning less than one year and "1" meaning greater than one year. Barriers which were reported to have prevented a person from obtaining care were dichotomized as "0" meaning no barriers and "1" meaning one or more barriers were reported. Design effects were

Original sample size is 1109 because only those who reported encountering a barrier are included. Controlling for visit greater than one year and listwise deletion of missing variables reduces the N to 304.

Standard errors adjusted when design effect >1.

computed using SESUDAAN, which incorporates the Taylor Approximation Method. Standard errors were then adjusted when design effects were greater than one.

Utilization Barriers Encountered as Dependent Variable—Regressions were run separately for each age-gender group using utilization of health services in the past year as a control variable (see Table 3).

Among persons who have visited a physician within the past year, the strongest variable associated with encountering barriers among Mexican American men ages 20–45 years was marital status, with married men encountering more barriers to health care. Among Mexican American men ages 46–74 years, those with less years of formal education, those with no regular source of care, and those with functional impairments encountered more barriers than others. For Mexican American women ages 20–45 years, poorer perceived health status, low income, and not having a regular source of care were associated with encountering barriers when seeking care. Among Mexican American women 46–74 years of age, the less acculturated, the uninsured, and those with functional impairments encountered more barriers than others.

For Mexican American men ages 20–30 years who have not visited a physician for one year or more, lack of health insurance coverage and poorer perceived health status were associated with encountering barriers. There were no associations of consequence for Mexican American men 31 years of age and older. For Mexican American women ages 20–30 years, those with no health insurance coverage and those in poorer perceived health status encountered more barriers than others. Among Mexican American women ages 31–45 years, those with low incomes and those in poorer perceived health status encountered more barriers; for Mexican American women ages 46–74 years, being married and having less years of education were associated with encountering barriers when seeking health care.

Barriers Which Prevented Health Care as Dependent Variable—Multiple logistic regression analysis was the method of choice employed to examine the contributions of the predisposing, enabling, and need variables because of the skewed distribution and dichotomy of the dependent variable. Utilization of health services in the past year was again used as a control variable. Table 4 displays the results of this analysis which included only persons who reported encountering a utilization barrier.

Results indicated that, among Mexican Americans who saw a physician within the past year, those with lower incomes and those with functional impairments were more likely to be prevented from obtaining care than others. Among Mexican Americans who had not visited a physician within the past year, younger persons, women, and those in poorer perceived health status were more likely than others to have been prevented from obtaining health care.

Discussion

Findings from the HHANES revealed that approximately one-third of the adult Mexican American population had reported barriers to obtaining health care during their most recent medical encounter. These barriers to receiving health care were significant in that three-fourths of the time the barriers encountered were sufficient to prevent persons from obtaining the medical care they sought.

Analyses revealed that Mexican Americans with low educational levels and low incomes are experiencing more problems than other Mexican Americans in accessing health care. Spanish-speaking, foreign-born, and less acculturated Mexican Americans were found to be the most likely to be prevented from obtaining the care they sought.

A significant minority of the adult Mexican American population reported encountering barriers which prevented them from accessing medical care. Almost one in five adult

Mexican Americans reported the cost of medical care was a barrier to their receiving care. The concern over the cost of health care among Mexican Americans would appear to be warranted, given that they have the highest rate of being uninsured for medical expenses in the country.[2] A smaller proportion of the adult Mexican American population reported problems accessing medical care due to the lack of health care services during nonworking hours (e.g. losing pay from work, hours of operation were inconvenient, care was not available when needed). Occupational analyses were not performed; however, it may be that access to medical care is more dependent upon the availability of expanded hours of operation among health providers due to the greater propensity of Mexican Americans to be employed in hourly-paid service occupations.

Given the shortage of minority and multilingual health providers in the United States, it was encouraging to find that fewer Mexican Americans reported cultural or linguistic barriers to care (e.g., no Spanish-speaking staff, no Hispanic staff, disrespectful staff). This finding was unexpected given the body of research which has suggested that the exclusion of Spanish-speaking and/or Hispanic staff members is a primary reason for underutilization of health services among Mexican Americans.[4,6,22–24] This finding does not refute the probable importance of cultural and linguistic aspects of medical care but rather may signify that among Mexican Americans the cost, availability and accessibility constraints may be more important in determining utilization of health services than the cultural and linguistic constraints (as measured in the HHANES). It is possible that accessibility and availability of care (cost, geographic location, hours of operation, etc.) are most closely related to utilization of services while cultural and linguistic aspects of care relate more to satisfaction with care, compliance with treatment, continuation in treatment, etc.

It is unfortunate that Mexican Americans with the highest need for health care (poor perceived health status and functional limitations) tended to report the highest rates of encountering barriers which prevented them from obtaining the needed care. Also, approximately 6 percent of the adult Mexican American population reported not knowing where to go for health services or having a way to get there. Health providers and agencies seeking to increase access to medical care among Mexican Americans can assist by focusing on service delivery aspects (e.g., cost of care, providing convenient hours for the community they serve, decreased waiting time, etc.) and outreach aspects (educational and transportation) to reach those individuals who may not know where to go for care. It is possible that such efforts would increase access to care for all ethnic/racial groups.

ACKNOWLEDGMENTS

This investigation was funded in part by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC.

V. Utilization of Curanderos by Mexican Americans: Prevalence and Predictors Findings from HHANES 1982–84

JOHN C. HIGGINBOTHAM, MPH, FERNANDO M. TREVIÑO, PHD, MPH, AND LAURA A. RAY, MPA

Abstract: Data from the Southwest sample of the Hispanic Health and Nutrition Examination Survey (HHANES) were analyzed to examine whether the use of a curandero or other folk medicine practitioner hindered, enhanced, or did not affect the utilization of western health care services by Mexican Americans. Findings revealed that only 4.2 percent of the HHANES sample persons between the ages of 18–74 years reported consulting a curandero, herbalista, or other folk medicine practitioner within the 12 months prior to the survey. Income, self-perceived health status, the language of the interview, and dissatisfaction with modern medical care recently received independently predicted curandero utilization (adjusted OR 2.01 and 1.66, respectively). Low income and self-perceived health status were less strongly related to curandero utilization. [*Am J Public Health* 1990; 80(Suppl):32–35.]

Introduction

Mexican Americans have long been thought to be in generally poorer health than White non-Hispanics as evidenced by shorter life expectancies, and higher infectious, parasitic disease, infant and maternal mortality rates; they appear to be in better health than Black non-Hispanics whose socioeconomic conditions are generally comparable.[1,2] Recent evidence indicates that these disadvantages are diminishing.[3–6] Less progress has been made, however, for those conditions usually associated with a lack of access to health care, such as tuberculosis and diabetes.[2,7–9]

Despite their apparent health needs, Mexican Americans have not achieved expected levels of health care utilization. Unlike Puerto Ricans and Cuban Americans who exhibit higher levels of health care utilization than other White Americans, Mexican Americans demonstrate the lowest level of health care utilization of all ethnic/racial groups (for whom there are data).[6] This underutilization of modern medical care has occurred despite factors which in other groups have been indicative of higher utilization rates (e.g., the stress factors of poverty, acculturation, and crowded housing).[10]

Alternative hypotheses to account for this underutilization include:

- cultural and language differences between patient and provider;
- folk medicine practices as an alternative to that of the modern health care system;
- environmental and socioeconomic conditions creating priorities for daily living inconsistent with the fee-for-service modern health care system.[11]

Contradictory results have been reported on why Mexican Americans underutilize health care services. Some of this research, particularly concerning the use of folk medicine, has been considered a disservice to Hispanics because it focuses on cultural or attitudinal explanations for underutilization while ignoring other possible explanations such as those associated with socioeconomic factors and lack of access to care.[12]

Andersen, *et al*, posited that Hispanics have limited access to medical care due to low levels of income, education, and health insurance coverage.[13] Treviño and Moss found that Mexican Americans with health insurance are 1.5 times more likely to consult a physician than Mexican Americans without insurance.[14] In addition to the monetary restraints, Chesney, *et al*, suggested that acculturation and social isolation are pertinent barriers to medical care for Mexican Americans.[15] While the debate continues as to what the exact barriers to health care are for Mexican Americans, the general consensus is that for Mexican Americans the availability of health care (as distinct from access) is comparable to that of the population in general.[13]

All societies have some systematized manner in which to deal with illness.[16] In the past some Mexican Americans have utilized curanderos or folk medicine practitioners. The number of Mexican Americans who still use curanderos as an alternative to modern medical care, for cultural and/or economic reasons, is unknown.

Most studies of curanderismo, the practice of folk medicine, have sought to describe and evaluate this phenomenon by indirect methods, i.e., through studies focused on the practitioner's patients.[17,18] These studies have produced detailed descriptions of the specific healing techniques used[19] or information on the type of disorder being treated.[17] Little is known about the prevalence of their use by Mexican Americans and what factors differentiate users from nonusers. Such factors could include cultural orientation, ability to pay, and dissatisfaction with previous medical care. It is unknown whether curanderismo is used as an exclusive alternative to modern medicine or whether both types of care are used concurrently.

This study seeks to compare those Mexican Americans (ages 18 years and older) in the Southwestern sample of the HHANES who reported consulting a curandero, herbalista, or other folk medicine practitioner within the last 12 months with those who did not do so. A model to predict those who sought alternative care is formulated.

Methods

The Hispanic Health and Nutrition Examination Survey (HHANES), the first national study of the health of the Hispanic population, was conducted during 1982–84 by the National Center for Health Statistics. A more detailed account of the design is presented elsewhere.[20,21] The HHANES sought to obtain representative samples of Hispanics households by concentrating sampling procedures for Mexican Americans in five southwestern States.

Specifically, this analysis includes those Mexican Americans, ages 18 years and older, who responded to the question

NOTE: Author affiliations are listed elsewhere under CONTRIBUTORS.

"There are some providers of health care that we sometimes go to, such as curanderos, sobadores, herbalists, spiritualists, and others. Have you seen or talked to any of these persons for health care during the past 12 months?" There are significant differences between curanderos, herbalistas, and other folk medicine practitioners; however, all were included in the single question used in HHANES to access folk medicine utilization. Further, they all represent a traditional medicine alternative to "scientific" medicine. Henceforth in this report, curandero will be used to refer to all of these folk medicine practitioners.

Due to the nature of these data, efforts were undertaken to account for the large size and method of sampling in the analysis. Design effects have been accounted for through the reporting of weighted percentages and adjusted variances, which were computed utilizing the Taylor approximation of the SESUDAAN methodology.[22] Comparisons were made between weighted and unweighted estimates resulting in insignificant variation, sample sizes are presented unweighted while statistical test and percentages utilize weighted estimates.

The variables used in the prediction model were drawn from the literature. They included indicators of: health status, ability to pay for health care, and health care utilization (see Appendix for details of these items), as well as the demographic variables of gender, age, marital status, education, nativity, acculturation, language of interview, family size, and size of the respondent's community or city of residence.

Descriptive and multivariate analyses, including logistic regression (using SAS, Proc Logist; SAS Institute, Inc.), were performed on the data in order to build the model which best predicted curandero utilization with the fewest variables. Odds ratios and 95 percent confidence intervals, using adjusted standard errors, were calculated from beta coefficients.[23]

Results

The total sample size for this investigation includes 3,623 Mexican Americans from the Southwestern United States ages 18 years and over. Of this number, only 148 persons (4.2 percent) reported consulting a curandero, herbalista, or other folk medicine practitioner within the last 12 months.

Users of curanderos were slightly more likely to be male, less well educated, and foreign born (Table 1). Marital status, age, family size, geographical distribution, or size of the community in which they reside were not found to be related to the use of curanderos.

Acculturation was not found to be significantly related to use of curanderos. Subsequent analysis, however, revealed that being interviewed in Spanish was found to be highly predictive of curandero utilization, whereas nativity was not.

Table 2 presents the comparisons of proportions on indicators of health status by users and non-users of curanderismo. During the physical examination portion of the HHANES, the physician was asked to indicate his/her global assessment of the respondent's health status. The vast majority (>85 percent) for both groups were classified by the physician as being in very good or excellent health. There were no differences in physician assessment of health status of Mexican Americans who used curanderos and those who did not utilize them.

Those who consulted a curandero were more likely than those who did not to report their current perceived health status as fair or poor and to believe they had little control over their future health status.

TABLE 1—Demographic Characteristics of Reported Users and Non-Users of Curanderismo

	% Users	% Non-Users

100,000–499,999	14.4	15.0
25,000–99,999	28.2	27.5
200–24,999	21.7	24.1
Not in a place	7.9	9.2

Those who consulted curanderos in the last year were found to be less satisfied with the care they received at their last visit to a medical practitioner. However, no differences were found regarding having a regular source of care or recency of last visit to a medical practitioner (Table 3). Further, poverty status, the presence or absence of health insurance coverage or the type of coverage were not found to be related to use of curanderos (Table 4).

Logistic regression with backward elimination was applied to this sample in order to delineate which variables out of this theoretical framework were most predictive of curandero utilization. Those variables that remained within the model were: satisfaction with care received at last visit, the language of the interview, self-perceived health status and income (Table 5).

Discussion

As noted by others,[16] relatively few persons of Mexican origin in the United States consult a curandero. Only 4 percent of the adult Mexican Americans interviewed in the HHANES reported that they had consulted a curandero within the past 12 months. Comparable population estimates

*These variables were found to be significant in the logistic regression model but use of adjusted standard errors in calculation of the CI included the null value.

for utilization of folk healers in other ethnicities are not available in the literature.

Mexican Americans may be reluctant to discuss use of curanderos and this could have an impact on the findings of this investigation. However, bilingual interviewers of predominantly Hispanic origin were used in the HHANES. While some reluctance to answer questions regarding curanderismo usage may have occurred, the level of reluctance is thought to be decreased by the cultural and linguistic similarity between the interviewers and the sample persons.

It has been hypothesized[13] that, as a consequence of the use of curanderos, Mexican Americans tend to delay seeking medical care, often until the condition becomes critical. The data presented here do not support that view. If this were true, then differences in time since last health care visit and health status would be evident in the two groups compared. This was not found to be the case.

Regression analyses revealed that adherence to a Mexican cultural orientation (in the form of preference to be interviewed in Spanish) and dissatisfaction with medical care received were related to use of curanderos while ability to pay and availability of care (as indicated by the reporting of a regular source of care) were not so related.

It is possible that those persons who spoke Spanish during the interview are experiencing greater difficulty communicating with health care professionals (predominantly monolingual in English) hence are more dissatisfied with the care they received and seek an alternative source. It is reasonable to assume that those persons who do not have the expendable income to "shop" for a physician would also be more likely to show dissatisfaction with care and seek an alternative source of care, accounting for the marginal predictability of income. Similarly those who feel that they are in poor health may be somewhat more likely to seek persons with whom they can communicate more easily, and whom they perceive as being more empathetic—in this case, curanderos.

This research has been a first step in trying to unravel complex relationships. A major limitation of this research involves the small number of Mexican Americans who reported consulting a curandero; this precluded an examination of possible interactive variations which may have occurred with respect to curandero use. Nevertheless, the data indicate that few Mexican Americans consult folk medicine practitioners, and that those who do so also consult physicians. The research suggests that health care professionals should maintain and strengthen their efforts to deal with linguistic and cultural differences in order to be as effective as science allows.

APPENDIX

Variables Used in the Analyses

Perceived control of future health status was derived from the following question: "How much control do you think you have over your future health: a great deal, some, very little, or none?"

Income was derived from the following question: "Was the total combined family income during the past 12 months more or less than $20,000? Include money from jobs, Social Security retirement income, unemployment payments, public assistance, and so forth. Also include income net from interest, dividend, income from business, farm or rent, and any other money income received."

Determination of insurance coverage was an amalgam of several questions. A positive response to one or more of the following would indicate the presence of coverage, a negative response to all would indicate the absence of insurance coverage:

- "Is sample person now covered by Medicare?"
- "Does sample person have a Medicaid card?"
- "Is sample person now covered by any other public assistance program that pays for health care?"
- "Is sample person now covered by CHAMPUS, which is medical insurance for dependents or survivors of disabled veterans?"
- "Is sample person now covered by any other program that provides health care for military dependents or survivors of military persons?"
- "Is sample person covered under this plan?" (referring to for-profit health insurance plans to which they or their employer may subscribe).

Type of insurance coverage was determined by the presence or absence of preceding items. Not covered by insurance is equivalent to no insurance coverage above.

The *poverty level* variable was a dichotomization of those at or above and those below the poverty index. The poverty index is a ratio of two components: the numerator is the midpoint of the income bracket reported for each family; the denominator is a poverty threshold which varied with the number of persons in the family, the adult/child composition of the family, the age of the reference person, and the month and year in which the family was interviewed.[20]

The *time since last visit* was determined by the compilation of two questions:

- "Now I would like to ask you some questions about your last visit to the (care source as previously determined). How long has it been since that visit? Less than one month; one month but less than six months; six months but less than one year; one year but less than five years; more than five years."

A second question has the same response categories with the addition of the choice of "never", and it reads:

- "Now I would like to ask you some questions about your last visit to any clinic, health center, doctor's office, or other place for health care. How long has it been since your last visit for health care?"

The *source of care variable*, speaking of the "scientific" source of health care, comes from three questions:

- "Is there a particular clinic, health center, doctor's office or other place that you usually go to if you are sick or need advice about your health?"
- Have you visited any other clinic, health center, doctor's office or other place for health care since your last visit to the (regular source)?"
- "How long has it been since your last visit for health care?"

A positive response to the first question and a negative response to the second indicates a regular only source of health care; positive responses to both questions indicates a regular and other source of health care; those who responded positively to the second question but negatively to the first indicate other source only; and, a response of "never" to the third question indicates that the respondent has never visited any source of health care.

The *satisfaction with care variable* is derived from the question:

- "In general, how satisfied were you with the care you received at that visit?" Would you say you were very satisfied, some what satisfied, or not at all satisfied?"

ACKNOWLEDGMENT

This investigation was funded by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC.

VI. Alcohol Consumption Patterns among Mexican American Mothers and among Children from Single- and Dual-Headed Households: Findings from HHANES 1982–84

CHRISTINE A. STROUP-BENHAM, MA, FERNANDO M. TREVIÑO, PHD, MPH, AND DOROTHY B. TREVIÑO, PHD

Abstract: Data from the southwestern United States sample of the Hispanic Health and Nutrition Examination Survey were employed to compare the patterns of alcohol use among Mexican American mothers and children in female-headed households with use patterns among mothers and children in couple-headed households. Single female heads of household drank more alcoholic beverages on more days than females from dual-headed households. As a whole, the children of single heads of household still living at home did not demonstrate significantly different drinking patterns from their dual-headed household counterparts. While male children of single-headed households drank more days and total drinks than their dual-headed household counterparts, female children of dual-headed households drank more days and total drinks than female children from single-headed households. [*Am J Public Health* 1990; 80(Suppl):36–41.]

Introduction

The number of single female-headed families in the United States has been increasing during the past three decades. By 1984 over 25 percent of all families that included children were female-headed.[1] Data from Bean and Tienda[2] indicate that 36.5 percent of Puerto Ricans, 18.9 percent of Mexican Americans, and 16.0 percent of Cuban Americans lived in single female-headed families in 1980.

Studies indicate that Hispanic female-headed families are exposed to a variety of potential stressors, such as poverty,[3,4] lack of health insurance,[5] lack of child health care,[6] and lack of social support.[6,7] This suggests they may also be at higher risk for behaviors that have been associated with higher levels of stress, such as alcohol use. Women who had never been married or who were divorced or separated have been found to have lower rates of abstention and higher rates of heavier drinking,[8] especially if cohabitating.

In our analysis of the Hispanic Health and Nutrition Examination Survey data, we attempted to determine if mothers and children in female-headed households (i.e. no male head of household present) displayed alcohol drinking patterns that reflected a greater quantity and frequency of alcohol consumption than did the drinking patterns among the mothers and children from dual-headed households (i.e. both mother and father present) and if factors such as age, acculturation level, education level, and socioeconomic status modified any such relation between household type and drinking patterns. Previous studies[9] have suggested that such factors are partially responsible for differences in behavior observed among single female heads of household and females from dual-headed households.

Methods

The Sample

The Hispanic Health and Nutrition Examination Survey (HHANES) was conducted from 1982 to 1984 by the National Center for Health Statistics (NCHS). The objective of this survey was to secure a representative sample of approximately 12,000 Hispanics in three geographic areas: the southwestern United States, Dade County, Florida, and the New York City metropolitan area.[10] Our research was limited to Mexican Americans (i.e. those with a national origin recode of 1) from the Southwestern sample, since there were fewer cases of single female-headed families among the Cuban and Puerto Rican populations.

The analyses were restricted to those single female-headed (246) and dual-headed (1,022) families in which the mother and at least one of her children under 19 years of age at the time of the interview were sampled (the analytic sample consists of mothers and all of their children who were included as sample people in the HHANES). This strategy assured greater comparability with other investigations of household headship.[11]

Each individual included in the HHANES does not represent the same number of individuals in the actual population, since certain age groups were under- or over-sampled. Therefore, sample weights were used in order to generate correct estimates.[10,12] All analyses were conducted both unweighted and weighted. The unweighted Ns and the weighted statistics are reported unless otherwise stated.

Measures

Individuals ages 12 to 74 were asked questions about alcohol use in the Adult Person Supplement Questionnaire of the HHANES, including:

- on how many of the prior 28 days they had consumed any beer, wine, or liquor;[13]
- total number of drinks (rather than days) summed across all alcohol types consumed during the reference period. One single female head of household (28 years of age, employed, tenth grade education, and living below the poverty level) reported consuming a total of 789 alcoholic drinks during the 28-day reference period;
- the average number of "drinks per occasion" (computed, by dividing the total number of alcoholic drinks consumed during the reference period by the total number of days the subject drank).

Those who had drunk any type of alcohol during the reference period were classified as "drinkers," all others were "abstainers." In females, "high drinking" was defined as having an average of four or more alcoholic drinks per occasion during the reference period and "low drinking" was defined as having one to three drinks per occasion. In males, the corresponding definitions were six or more and one to five. These created variables parallel those employed by Markides, *et al*, in their 1988 three-generation study.[14]

NOTE: Author affiliations are listed elsewhere under CONTRIBUTORS.

The HHANES included a modified version of an acculturation scale developed by Cuellar, *et al*,[15] which has been extensively utilized among Mexican American populations. The modified scale is comprised of eight items pertaining to language preference, language spoken, language subject reads better, language subject writes better, ethnic identification of the subject, ethnic identification of the subject's mother, ethnic identification of the subject's father, and one item that combined the place of birth of the subject's parents. This scale has a minimum value of 1 and a maximum value of 4.9, with higher scores indicating higher levels of acculturation.

Age refers to the actual age of the individual at time of examination. Education is the number of years of school completed. Employment status was coded 1 for employed (part- or full-time) and 0 for non-employed. Poverty was coded as 1 for persons living below the federal poverty cut point and as 0 for those at or above poverty level. Income reflects the combined family income (categorized) over the 12 months prior to the interview. All of the dual heads of household were self-identified as a spouse of a head of household or as head of household with a spouse.

None of these variables had a non-response rate of greater than 10 percent for the mothers and 12 percent for the children. The majority of the questions were answered by nearly all subjects in the sample. Therefore, the effects of non-response are believed to be minimal.

Analyses

The variables (total drinks, total number of drinking days, and drinks per occasion) were examined within each household type for three age categories among the mothers, 17–29, 30–39, 40–74 (approximate tertiles), using analysis of variance.

Analysis of covariance was employed to test the hypothesis that mothers and children of single-headed households would consume more alcohol than those in dual-headed households when controlling for age, acculturation, combined family income, and education. Multiple classification covariance analysis (see, e.g., Nie, *et al.*[16]) produces adjusted means across the values of each independent variable. Analysis of covariance (ANCOVA) employed total number of drinks as the dependent variable with dual vs single household type as the independent variable. The covariates—including combined family income, acculturation level, education level, and age—were then entered into the procedure. Adjusted means were obtained for each level of the independent variable. This same procedure was employed for two additional ANCOVAs using, respectively, the dependent variables of total number of days drank and number of drinks per occasion.

Analysis of covariance was also employed to explore children's drinking patterns. Three separate analyses were conducted, using total number of drinks, total number of days, and number of drinks per occasion, respectively, as the dependent variables and household type as the independent variable. The covariates in each analysis were age, education, gender, combined family income, and acculturation.

Regression coefficients and their standard errors are presented for the covariates of each analysis of covariance. Standard errors have been adjusted for design effects[10,12] (design effects were calculated employing the Taylor approximation technique available with the SESUDAAN program[17]).

Results

An examination of marital status indicated that the majority of single female heads of household were divorced (34.5 percent) or separated (33.1 percent). The remainder of the single females were either widowed (18.1 percent) or had never been married (14.3 percent). Examination of the marital status of the children of these women revealed that just nine were married and four were separated while the remainder had never been married. Tables 1 and 2 present weighted means and percents for the alcohol variables as well as sociodemographic characteristics of mothers and children controlling for household type. More single mothers (and their children) were living in poverty and were more likely to be employed in comparison with their dual-headed counterparts (Table 1). The observed differences between mothers and children regarding percent impoverished and family size are a function of a lack of a one-to-one correspondence between mothers and children (The statistics would be the

SOURCE: NCHS Hispanic Health and Nutrition Examination Survey same if there was a one-to-one correspondence.)

There were 92 single female heads and 214 females of couple-headed households who were drinkers; 29 children who were drinkers were in single households and 84 were in dual-headed households; 46 percent of the single female heads of household who were drinkers were high drinkers compared to 24 percent of the female drinkers in dual-headed households (Table 2). Examination of the percentages of drinkers across marital status of single female heads of household indicated that there were a greater proportion of drinkers among those who were divorced (47.9 percent) or separated (41.0 percent) than those who were never married (33.3 percent) or were widowed (32.9 percent).

When sociodemographic characteristics of mothers from single and two-parent households were examined controlling for drinker type (i.e. abstainer vs drinker), families of drinking women tended to be smaller than families of abstaining women. Women who were drinkers had higher education levels and were less likely to be impoverished than abstainers. Drinkers from both household types had a higher level of acculturation and a greater percentage employed than abstainers. The analysis of variance (ANOVA) procedures indicated that there were no significant differences between the three age categories of mothers in single- and dual-headed households for the dependent variables of total number of days drank, total number of drinks, and drinks per occasion.

The proportion of children living in poverty was less among drinkers than abstainers. The children who were drinkers were slightly older. In order to determine if the proportion of drinkers varied across age groups among the children, the percentage of drinkers in three age categories (i.e. 12–14, 15–16, 17–19 years) was computed. While cell sizes were small for the youngest age categories, no significant differences in the percent of drinkers across age groups were found, even when controlling for household type.

Results of the ANCOVA procedure indicated that the weighted crude mean total drinks for single heads of household was 13.17 and for females of dual-headed families it was 2.46. When the covariates—highest level of education achieved, combined household income, age, and acculturation—were taken into consideration, the resulting weighted adjusted means were 21.91 drinks for singles and .32 drinks for duals (Table 3). The second panel of Table 3 provides the regression coefficients (bs) and standard errors (adjusted for design effects) of the covariates. These results indicate that household type had a strong negative association with total number of drinks consumed, meaning that single heads of household drank more than women from couple-headed families. Acculturation was found to have a positive relationship with total number of drinks, indicating that women who were more acculturated tended to drink more.

Single female heads of household drank a weighted mean of 2.12 days and females of couple-headed households drank a weighted mean of .92 days; adjusted weighted means were 3.34 and .62 days, respectively (Table 3). The strongest relationship found between covariate and number of days drank was a negative one with household type. The remaining three covariates had weaker positive associations with the dependent variable.

The adjusted weighted means of number of drinks among females per occasion were 6.06 for single household heads and 2.23 for dual household heads (Table 3). As with the previous analyses, household type was discovered to have a strong inverse relationship with the dependent variable, number of drinks per occasion.

Because one single female head of household reported 789 drinks for the 28-day reference period, we analyzed the data after excluding her. In addition, a logarithmic transformation of the three dependent variables was computed from the data (including this single head of household) because of the skewed distribution. These new values were utilized in the three ANCOVAs. These procedures produced results comparable to those shown in Table 3.

Since acculturation appeared to have the most influence (other than household type) with respect to the dependent variables, further analyses were undertaken to uncover its relationship with these measures. It was found that among both single and dual female heads of household, acculturation levels were significantly higher among those who consumed more alcohol.

Analysis of covariance was also utilized to examine the children's (ages 12 to 18 years) continuous drinking measures. Covariates included age, education, gender, combined

family income, and acculturation level, with household type as the independent variable. The weighted adjusted mean number of total drinks during the reference period was 3.80 for children in single-headed households and 2.42 for children of couple-headed households, .75 and .68 respectively for total drinking days, 3.59 and 4.17 respectively for drinks per occasion (Table 4).

None of these ANCOVAs examining the continuous drinking variables for the children indicated that household type had a strong relationship with the dependent variables. However, all three analyses exploring the children's drinking patterns demonstrated strong associations between the covariates age, sex, and acculturation and the dependent variables (Table 4). In order to discover how these covariates were related to the continuous drinking variables, several analyses were done. Male children of single heads of household were found to drink more and on more occasions than male children from two-parent homes (Table 5). Whereas, female children of dual-headed households drank more than those from single households. No significant differences were found between high vs low drinkers or abstainers vs drinkers with respect to level of acculturation or age. Drinking children were slightly older than non-drinking children in both single- and dual-headed households (16.4 years compared to 14.5 years).

In order to determine if drinking status among children was related to drinking status of mother, proportions of drinking children (controlling for gender) were computed for abstaining and drinking mothers of each household type. As shown in Table 6, percentages of drinking daughters were similar among abstaining mothers from couple-headed households (11.9 percent) and abstaining single heads of household (9.2 percent). A greater proportion of drinking daughters came from two-parent homes with a drinking mother (23.3 percent) than came from single-parent homes with a drinking mother (11.5 percent). Among single-headed families with abstaining mothers, 35.6 percent of the sons were found to drink, while 16.9 percent of the sons from dual-parent homes with abstaining mothers did so. Within single-parent families having a drinking mother, 20.7 percent of the sons drank. It was found that 26.2 percent of the sons in two-parent homes with a drinking mother were drinkers also. Analyses indicate that these gender differences do not appear to be related to a variation in age distribution.

Discussion

As hypothesized and as found in other ethnic groups, there was greater use of alcohol among parents in non-intact families compared to those from intact families,[18,19] even when age, acculturation level, education, and income were taken into consideration. Acculturation did appear to play a role in drinking behaviors, since women drinkers of both single- and dual-headed households had higher levels of acculturation.

It has been suggested in other studies that more acculturated Mexican American women do have a tendency to have higher alcohol consumption.[13,14,20,21] Higher levels of acculturation do not explain why single female heads of household consume much more alcohol than their dual counterparts, however. Stressors of being a single female head of household need to be explored to ascertain what, if any, role they have in exacerbating drinking behaviors of single female heads of household.

It has been suggested by others[9] that when socioeconomic status is controlled, differences between single- and dual-headed households become non-significant. However, this study does not support such findings with respect to alcohol consumption patterns. In fact, we found that when such factors as income and education are controlled for, the differences between women of the two household types became more pronounced. Therefore, other elements must be contributing to the heavier alcohol consumption among single female heads of household. This conclusion is supported by the relatively small values of the adjusted R^2's for the ANCOVAs—suggesting that the independent variables explain little of the variance.

Since we have no data on initiation of alcohol use in conjunction with changes in marital status, it may be that marriage breakdown was due partially to the drinking behav-

iors of these females or that being single allowed these women more opportunity to consume alcohol.

The findings regarding female children are surprising. One would expect that daughters of single female heads of household would drink more than daughters of dual household heads, but we found the reverse to be the case. Additionally, sons of abstaining single mothers were more likely to be drinkers in comparison with both sons of abstaining dual mothers and sons of drinking mothers of either household type. Of course, within couple-headed families, children have a father who may act as a role model for their drinking behaviors. This could explain the findings regarding children if fathers were more likely than mothers to be drinkers.

In summary, these data suggest that single female heads of household drink significantly more than women in couple-headed families. This research indicates that single female heads of household are at increased risk for greater consumption of alcohol. While a lower percentage of mothers from couple-headed households consume alcohol, their numbers are greater. This information may be of assistance to those who implement preventive and intervention measures and treatment, especially since data indicate that alcohol-related mortality is particularly high among Mexican Americans.[22] Additionally, further research needs to be done to investigate the factors contributing to the drinking behaviors among these women, such as change in marital status and psychological stressors. In this way, treatment and intervention may become more effective.

ACKNOWLEDGMENTS

This investigation was funded by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC. Support was also received from the IUP/SSRC Grant Program (#2675021920) and a grant from NIMH (DHHS 5 RO1 MH 44214–02).

VII. Acculturation and Alcohol Consumption in the Mexican American Population of the Southwestern United States: Findings from HHANES 1982–84

Kyriakos S. Markides, PhD, Laura A. Ray, MPA, Christine A. Stroup-Benham, MA,
and Fernando Treviño, PhD, MPH

Abstract: Data from the Southwestern sample of the Hispanic HANES are employed to evaluate the relationship of acculturation into the larger society with alcohol consumption. As in previous work, acculturation was not found to be related to alcohol consumption of Mexican American men, but was positively related to the consumption of younger Mexican American women. Among middle-aged women, acculturation was not important. However, we found evidence that middle-aged women might be turning to alcohol in response to marital disruption and poverty. In addition, middle-aged women who are not employed are less frequent drinkers but those who drink are heavier drinkers than employed women. [*Am J Public Health* 1990; 80(Suppl):42–46.]

Introduction

In recent years, a number of papers focusing on predictors of alcohol consumption among Mexican Americans have been published. By far, the leading predictor of interest has been "acculturation" into the larger society.[1–4] The concept of acculturation has actually assumed great importance in studies of Mexican Americans in general during the 1980s, particularly in research on mental health.[5,6] Despite its increasing importance, little progress has been made in both conceptualizing and measuring acculturation.

Gilbert and Cervantes,[2] who have reviewed much of the literature on acculturation and alcohol consumption among Mexican Americans, have suggested two models generally followed.

- The *acculturative stress model,* according to which higher and/or more frequent alcohol consumption is the result of the many stresses accompanying the process of acculturation into the larger society. Higher drinking would thus be expected in persons at the middle of the acculturation continuum, and not at the extreme ends.
- The *acculturation model*, on the other hand, predicts that alcohol consumption patterns of Mexican Americans would reflect the extent to which they have adopted the drinking norms and practices of the larger society.

The literature has been mixed with regard to support of these perspectives.[1–2,4] In general, however, it appears that the "acculturation" model tends to be more predictive of the behavior of women.[1,2] With regard to men, the literature has been less clear-cut.[1]

Working from these two perspectives, Markides, *et al*,[3] hypothesized that the "acculturative stress" model would have relevance to the drinking experience of men, while the "acculturation" model would have more relevance for women. The latter hypothesis was based on the relatively low drinking rates of Mexican American women. Since, as a group, they drink little, women would be less likely to turn to alcohol as a way to relieve any stress associated with acculturation.

Markides, *et al*,[3] tested these hypotheses using data from a three-generation study of Mexican Americans living in the San Antonio area. Among men, they found that acculturation was related to lower alcohol consumption in the middle generation (middle-aged people). Since virtually all of the middle-generation subjects were born in the United States, people at the low end of the acculturation scale were at the middle of the acculturation continuum, and thus, the results were interpreted as consistent with the "acculturative stress" hypothesis. Among women, acculturation was positively related with alcohol consumption in the younger generation, as predicted by the acculturation hypothesis. However, middle-generation women behaved much like their male counterparts as they appeared to drink more if they were less "acculturated."

This paper attempts to replicate the above study using data from the more representative southwestern United States sample from the Hispanic Health and Nutrition Examination Survey (HHANES). Thus, the analyses are conducted separately by sex and for three age groups: 20–39, 40–64, and 65–74 years. These correspond roughly with the ages of the three-generations in Markides, *et al*.[3] However, the middle and younger age groups have more variation on acculturation since they also include first-generation (foreign-born) Mexican Americans.

Methods

The data were collected as part of the Adult Sample Person Supplement of the southwestern sample of the Hispanic HANES.[5] Our analysis is limited to the Mexican American respondents from the five Southwestern States (Texas, New Mexico, Colorado, Arizona, and California). The Adult Sample Person Supplement Questionnaire contains a long series of questions regarding alcohol consumption. We used several variables which enabled us to construct similar measures to those employed by Markides, *et al*.[3] Respondents were asked how many days altogether they drank beer during the four-week period ending on the Sunday prior to the interview. Next, they were asked how many beers they drank per day during the days they drank beer. They were also asked how many beers they drank in total during the four-week period. These questions were repeated with regard to wine and with regard to "liquor such as: whiskey, rum, gin, vodka or tequila." Respondents were also asked on how many days they drank any kind of liquor.

Using the above information, we were able to create the following variables: *Frequency* refers to the number of days a person had consumed any alcoholic beverages during the 28-day reference period. *Volume* refers to the average num-

---

NOTE: Author affiliations are listed elsewhere under CONTRIBUTORS.

ber of drinks consumed per day by those who drank. *Total Drinks* refers to the total number of drinks consumed during the 28-day period by all respondents. *High Drinking* refers to the percentage of men who drank six or more drinks a day when they drank, and women who drank four or more drinks a day when they drank. *Drinkers vs Abstainers* refers to the percent of respondents who had drunk any alcoholic beverages during the 28-day reference period (coded 1 for drinkers and 0 for abstainers).

The key independent variable in our analysis is "acculturation." The Hispanic HANES utilized a shortened eight-item version of the Cuellar acculturation scale, which is the most widely used scale in research with Mexican Americans.[7] Items included captured the respondents' language use and preference, ethnic identification and nativity, both for the respondent and his/her parents. Internal consistency reliability for the scale is in excess of .90.

Other variables employed were more straightforward. *Age* was actual age at the time of the interview; *Education* refers to years of school completed; *Marital Status* was coded 1 for married persons (spouse present) and 0 for all others; *Poverty* was coded 1 for people living below the federal poverty line and 0 for all others; finally, *Employment* was coded 1 for persons who were employed (full-time or part-time) at the time of the interview and 0 for all others.

The five alcohol measures discussed earlier were regressed on the acculturation scale and the five control variables: age, education, marital status, poverty, and employment. The analysis was performed separately by sex and for three age groups: ages 20-39, 40-64, and 65 and over. As mentioned above, these age groups correspond roughly to the three generations in Markides, *et al*,[3] who have shown that the influence of acculturation on alcohol consumption varies by generation (age) and sex. All analyses were performed with appropriate adjustments for sample weights and design effects. Design effects were necessary because the Hispanic HANES employed a complex multi-stage probability sample design. Sample weights were normalized by multiplying the number of subjects in each age/gender group employed in the analysis with each respondent's weight divided by the sum of the weights for the group. Design effects were computed using the Taylor Approximation of the SESUDAAN program and were subsequently employed to adjust the variances in the regression analyses. Examination of correlation and covariance matrices did not reveal evidence of multicollinearity (Intercorrelation tables are not presented but are available from the authors upon request). Regression analyses employed listwise deletion of missing values which led to the loss of cases ranging from 9 to 15 percent.

The analysis is aimed at evaluating the usefulness of the "acculturative stress" and "acculturation" perspectives.[2] As mentioned earlier, we expect the former to have more relevance for men and the latter to have more relevance for women. However, based on our unexpected findings with middle-aged women in the three-generation study,[3] we also examine the possibility that some middle-aged women in this sample might resort to alcohol consumption as a way to relieve stress related to acculturation or other factors.

Results

Table 1 presents means and percents on the five alcohol measures described above by sex and age group. Maximum sample sizes for each group are shown at the top. These ranged from 1,016 younger females to 84 older males. Number of cases for the alcohol variables vary because of missing values and because nondrinkers are not included in the measurement of some variables. For example, volume is the average number of drinks per day when a person drank. Only people who had drunk during the 28 days prior to the interview are included. This means considerably small sample sizes, particularly among women and older people, most of whom are not drinkers.

As Table 1 shows, drinking is considerably more frequent and heavier among younger and middle-aged men as previous studies have shown. Although these men do not appear to be very frequent drinkers when compared with men in the general population, they drink heavily when they drink, which is consistent with findings from previous studies.[2,4,8]

TABLE 1—Alcohol Consumption Variables and Sociodemographic Variables by Gender and Age Group

	Ages 20–39		Ages 40–64		Ages 65–74	
Variables	Male (N = 822)	Female (N = 1016)	Male (N = 558)	Female (N = 726)	Male (N = 84)	Female (N = 119)

Percent in Poverty	22.0	30.0	21.1	31.5	44.1	58.1
Acculturation	2.6	2.7	2.4	2.3	2.2	2.2
Percent Employed	94.2	53.5	84.1	45.9	13.5	6.8

Table 1 also presents data (means or percents) on several sociodemographic variables included in the regression analyses. As would be expected, acculturation is highest in the younger age group and lowest in the oldest. Also, the poverty rate is higher among women and the elderly. Other variables are distributed by sex and age as might be expected. As expected, consumption is much lower in the older age group, and much higher among men than among women in all three age groups.

Table 2 presents the results of the regression analyses for men and Table 3 of the analyses for women. The analyses were conducted separately for three age groups. The top panel of Table 2 shows the results for younger men (ages 20–39). As will be seen, acculturation is not associated with any of the alcohol variables in younger men. Of the other variables, marital status is negatively related to frequency and total drinks consumed (married men drink less); education is negatively related to volume of consumption and the probability of being a high drinker; similarly, living in poverty is positively associated with volume of consumption and probability of being a high drinker; finally, employment is associated with greater frequency of drinking.

The results for middle-aged men (Table 2) show no notable associations between acculturation and any of the alcohol measures. Age was negatively associated with the probability of being a drinker, while education was positively related with the same variable and with frequency of consumption. On the other hand, education was negatively associated with volume of consumption and the probability of being a high drinker. Married men had lower volume of consumption and consumed fewer total drinks and poverty was associated with less frequent consumption.

As would be expected, fewer associations were observed with older men, although this is partly the result of small numbers. Table 2 shows a negative association between age and the probability of being a drinker while marital status is positively associated with the same variable.

Table 3 shows the results for women. Among younger women, acculturation is positively associated with frequency of consumption and the probability of being a drinker. More educated younger women are more likely to be drinkers but they consume a lower volume of alcohol and are less likely to be high drinkers. Marital status is negatively associated with all five alcohol variables. Finally, employment is positively related to the probability of being a drinker.

Among middle-aged women, acculturation is positively related to the probability of being a drinker, but not to any of the other alcohol variables. Age was negatively associated with the probability of being a drinker, volume of consumption, total drinks consumed, and the probability of being a high drinker. Marital status was negatively associated with volume of consumption, the probability of being a high drinker, and the probability of being a drinker. Poverty was negatively associated with the probability of being a drinker; however, it was positively associated with volume of consumption and the probability of being a high drinker. Finally, employed middle-aged women were more likely to be drinkers and to be frequent drinkers. However, they consumed a lower volume of alcohol and were less likely to be high drinkers.

Among older women we find that education is positively associated with the probability of being a drinker. No other associations are noted but, again, the small number of cases is a problem.

Discussion

As shown in a number of previous studies,[1,2] acculturation is not related to alcohol consumption among men in any consistent manner. We expected a negative association between acculturation and alcohol consumption among men,

particularly in middle-age, as [illegible]he case in the three-generation study by Markides [illegible]l.[3] The lack of such negative association may very we[illegible] result from the higher variance on the acculturation scale among middle-aged men in this study than the second generation men in the three-generations study, virtually all of whom were born in the United States.

With regard to women, acculturation appears to be more predictive, as shown by previous research.[1–3] As found by Markides, *et al*,[3] a positive association is observed in younger women with both frequency and volume of consumption, as well as the probability of being a drinker. However, no association is observed among middle-aged women. Furthermore, no tendency is observed toward a negative association between acculturation and alcohol consumption in middle-aged women as was the case with middle-generation women in Markides, *et al*.[3] Although this difference might be again the result of greater variance in acculturation in the present study, there is no evidence that middle-aged Mexican American women are turning to alcohol as a way to relieve "acculturative stress." However, there is evidence that middle-aged women might be turning to alcohol as a way to relieve stress resulting from other factors, such as poverty and marital disruption. Thus, although poverty is negatively associated with the probability of being a drinker, among middle-aged women who drink, poverty is positively related to the volume of consumption, total number of drinks, and the probability of being a high drinker. Similarly, non-married middle-aged women (mostly divorced or widowed) were heavier drinkers. Finally, the effect of employment is in a direction suggesting heavier drinking among housewives, who are presumably more traditional. Even though middle-aged employed women were more likely to be drinkers and were more frequent drinkers, of those who were drinkers, housewives drank more heavily.

In sum, there is only partial support for an "acculturation" model with regard to alcohol consumption for women and no consistent support for an "acculturative stress" model for either sex. We hope to have demonstrated that the influence of acculturation on alcohol consumption among Mexican Americans is highly complex and depends on such factors as variation in the acculturation continuum, age, sex, and type of measure of alcohol consumption.

We believe that our findings also have implications for the broader literature on the health and mental health of Hispanics where a lively interest has been shown in the concept of acculturation. This research has yielded unclear results with regard to the role of "acculturative stress," because of conceptual and measurement problems, and difficulties in establishing exactly at which point on the acculturation continuum stress is at its highest.[7]

We also feel that studies of the health behaviors and health status of Mexican Americans and other ethnic populations will benefit from introducing a life course perspective into their approach to the data analysis. For example, there is evidence that the concept of acculturation has different meaning and influence at different stages of the life course,[10] as well as for the two sexes, as the present analysis has shown.

ACKNOWLEDGMENTS

This investigation was funded by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC. Support was also provided by the Alcohol Beverage Medical Research Foundation, the National Institute on Aging, and the Rockefeller Foundation. We would like to thank Hortensia Amaro and Amid Ismail for useful comments and suggestions.

VIII. Patterns of Cigarette Smoking among Hispanics in the United States: Results from HHANES 1982–84

Suzanne G. Haynes, PhD, Clair Harvey, Henry Montes, Herbert Nickens, MD, and Bernice H. Cohen, PhD

Abstract: In the 1982–84 Hispanic Health and Nutrition Examination Survey, the prevalence of cigarette smoking was examined among Mexican Americans, Puerto Ricans, and Cuban Americans in the United States. Among 20–74 years olds, the age-adjusted smoking rates for Mexican American, Puerto Rican, and Cuban American men were high—42.5, 39.8, and 41.6 percent, respectively. Quite striking among Cuban American men was the high smoking rate among 20–34 year olds (50.1 percent), the highest smoking rate in the three Hispanic groups compared. The age-adjusted smoking rates for Mexican American, Puerto Rican, and Cuban American women were much lower than those for men—23.8, 30.3, and 24.4 percent, respectively. Both Puerto Rican and Cuban American men were more likely to be heavy smokers (52.3 and 64.1 percent, respectively, smoking a pack or more a day) as compared to the Mexican Americans (33.8 percent smoking a pack or more a day). The pattern was the same for women, with Mexican American women being lighter smokers (18.8 percent smoking a pack or more a day) as compared to heavy smoking among Puerto Rican and Cuban American women (35.1 and 48.6 percent, respectively, smoking a pack or more a day). Given the health hazards of smoking, future research and intervention are required for those groups with high exposure to cigarette smoking. [*Am J Public Health* 1990; 80(Suppl):47–54.]

Introduction

In recent years, several studies have shown that the prevalence rates of smoking among Hispanics in the United States are relatively low in comparison to non-Hispanic Whites and Blacks. Most studies have examined Hispanic populations either in specific geographic areas or in particular ethnic groups, such as Mexican Americans in Sacramento, California[1–4] or in San Antonio, Texas.* National data have come primarily from the National Health Interview Survey (NHIS) which uses the term "Spanish Origin" to describe those of Hispanic ancestry.[5] These data may not reflect the true rate of smoking in the Hispanic US population since the NHIS data have not been collected with a Spanish language instrument nor have the interviewers been bilingual. In general, the number of Hispanics in most studies has not been large enough to be representative or to produce reliable estimates for analysis. This is particularly relevant if one attempts to disaggregate Hispanic data among various population subgroups, e.g., Mexican Americans, Puerto Ricans, and Cuban Americans.

The Hispanic Health and Nutrition Examination Survey (HHANES) was a probability-based survey of three distinct Hispanic populations in the United States.[6] For HHANES, the targeted population consisted of three groups of civilian noninstitutionalized persons ages six months to 74 years, from three areas of the US. The three groups were: 1) Mexican Americans residing in selected areas of Texas, California, Colorado, New Mexico, and Arizona (otherwise known as the Southwest); 2) Cuban Americans residing in Dade County (Miami), Florida; and 3) Puerto Ricans residing in the greater New York City area.

Smoking among Hispanics is currently gaining greater recognition as a public problem since cigarette manufacturers are now aggressively promoting cigarettes to the Hispanic population.[7,8] A recent report noted that these promotional efforts include advertisements in publications aimed at minority groups, sponsorship of entertainment and cultural events drawing large minority audiences, and extensive use of billboards in minority neighborhoods.[7]

Although the cigarette industry views this as an economic issue, for the Hispanic community it is more importantly an issue of maintaining a healthy population. A number of studies have documented the diseases associated with smoking, particularly for lung cancer and cardiovascular diseases. However, several studies have indicated a low incidence of lung cancer in Hispanics, which has been attributed to the low smoking rates of Hispanics in the study samples.[9–12] If the smoking rates of Hispanics are increasing, it would be tragic if Hispanic lung cancer rates reached parity with the majority population. Evidence for a significant rise in both lung cancer and COPD (chronic obstructive pulmonary disease) mortality rates in Hispanic males has been reported recently in New Mexico for the period 1958 to 1982.[13] These data serve as an early warning signal for the future health of Hispanics, particularly if cigarette smoking rises in this population.

Given the young median age of the Hispanic population (25.1 years vs 31.9 years for the total population) and rapid growth of this population (14.6 million in 1980 and 18.8 million in 1987),[14,15] the need to prevent smoking becomes even more critical in ensuring that high rates of disease are not in its future. Trevino and Moss[16] indicate the vulnerability of the Hispanic population to high morbidity and mortality rates due to the low utilization of health services and the fact that about 30 percent of Mexican Americans (the largest Hispanic group) are without health insurance. Other health care barriers such as language, transportation, and lower education levels add to this population's vulnerability and thus increase the need for developing sound risk factor reduction programs for the prevention and cessation of smoking.

Methods

HHANES Survey Design

Details of the HHANES sample design, selection process, operational plan, and quality control procedures have been documented elsewhere.[6] As noted in the foreword section of this supplement, the HHANES was a survey of three major Hispanic subgroups in selected areas of the United States[17] conducted over a two-year period (1982–84) in three regions of the United States: Mexican Americans in

five Southwestern states, Cuban Americans in Dade County (Miami), Florida and Puerto Ricans in the New York metropolitan area including parts of New York, New Jersey, and Connecticut. The sample design of HHANES was a stratified, multistage, probability sample of persons six months through 74 years of age. Data from all three portions of the survey are presented in this report.

The HHANES included both an interview and a three-hour medical examination conducted in a specially designed mobile examination center. Smoking history and other medical history data were collected during the household interview. The interviews were conducted in either English or Spanish, depending upon the language preference of the respondent. The vast majority of sample persons who stated they wanted to be interviewed in one language participated throughout the survey in that language. All persons ages 18 years and older responded to the questionnaires themselves unless they were physically or mentally unable to be interviewed.

The study population for this report included adults 20 through 74 years of age who met the eligibility criteria for Mexican American, Cuban American, or Puerto Rican, respectively. The analysis included those persons who completed the household interview and the medical examination. Persons not medically examined were excluded from this analysis because their smoking history responses could not be validated in the plasma cotinine study, to be described subsequently. Thus, we included only those persons for whom we could scientifically comment on the validity of the responses.

Of the 4,735 Mexican American adults ages 20–74 years who were sampled in the survey, 3,326 (70 percent) completed the household interview and medical examination, and were included in this report. Likewise, 865 (out of the sample 1,481) adult Cuban Americans and 1,220 (out of the sample 1,764) adult Puerto Ricans in this age range completed the two parts of the examination, reflecting response rates of 58.4 percent and 69.2 percent, respectively. Because these response rates are not high, as noted in the methodological paper to this supplement,[17] some caution in interpreting the results is advisable.

NHIS Survey Design

The 1985 National Health Interview Survey (NHIS) data presented in this report were analyzed by Marcus and Crane.[18] Their report was based on data collected in a continuing nationwide survey conducted on households representative of the US civilian noninstitutionalized population (one randomly selected respondent per household). Household members were interviewed by trained personnel of the US Bureau of the Census and information was obtained about the health and other characteristics of each respondent. In the 1985 NHIS, 33,045 respondents completed the smoking supplement. Standard NHIS protocols were followed in the survey, and response rates were approximately 95 percent.

In the NHIS survey, persons 17 years of age and over could respond for themselves and any responsible adult who was married or 19 years of age or older could answer questions for any other related person in the household, which may have led to some error in reporting.

Data Definitions

The cigarette smoking questions were asked of all adults during the household interview. A smoker was defined as anyone who had ever smoked at least 100 cigarettes in his/her life time. Current smokers included those among the smokers who smoked cigarettes at the time of the survey. The amount of cigarettes smoked was asked in terms of the usual number of cigarettes smoked per day, with packs equal to 20 cigarettes. The NHIS survey used similar definitions as those noted above. A validation of self-reported smoking with plasma cotinine levels was also conducted.[19] Respondents were also asked what brand of cigarettes they usually smoke.

Among the demographic variables examined in this study, education was grouped according to the highest grade or year of regular school the sample person completed. Income was defined as the total combined family income during the previous 12 months from any source. Acculturation was defined from the eight-variable scale, as described in the methodological paper for this supplement,[17] and was examined only in the Mexican American sample since the scale was not designed to assess acculturation levels of Puerto Ricans or Cuban Americans. Acculturation scores were divided into tertiles indicating low, medium, or high acculturation levels, with low acculturation indicating Mexican orientation, medium acculturation indicating bi-cultural bi-lingual, and high acculturation indicating US orientation.

Statistical Analysis

Sampling weights, specifically exam weights, were applied when calculating prevalence estimates in order to account for individual selection probabilities and adjustments for nonresponse, noncoverage, and post-stratification (Mexican American sample only) which resulted from the complex survey design used in HHANES. Each of the analytic variables was examined first using age-specific data. Since there were differences in the age composition of the three Hispanic populations, estimates were age-adjusted by means of direct standardization, using the United States 1980 Census population as the standard. These rates were computed using the program SESUDAAN.[20]

The complex survey design used in the HHANES tends to increase the variance which would have been obtained through simple random sampling.[21] As described by Kovar,[22] the design effect is the ratio of the variance of a statistic calculated from a complex sample to the variance of the same statistic calculated from a simple random sample. For HHANES, the average design effect for current smoking rates was 1.1 for Mexican Americans, .7 for Cuban Americans, and 1.3 for Puerto Ricans. Since these effects were all close to 1.0, the simple random sample variances were used in statistical testing unless noted otherwise. Two-tailed t-tests ($p < 0.05$) were used to compare point estimates. Standard errors presented in the tables were calculated using the SESUDAAN program, which takes the complex survey design into account. All data analyses were done using programs accessible through Statistical Analysis System.[23]

Since this paper is based solely on cross-sectional data, which does not allow us to investigate etiologic relationships, only descriptive statistics are presented. Multivariate analyses were not considered appropriate since the purpose of the paper was descriptive in nature.

Limitations

The cross-sectional design prohibits one from making antecedent-consequence statements, as well as from separating out any effects of selective survival on the responses. Persons who previously died because of cigarette smoking or could not participate in the examination because of illnesses due to cigarette smoking are not represented in our findings.

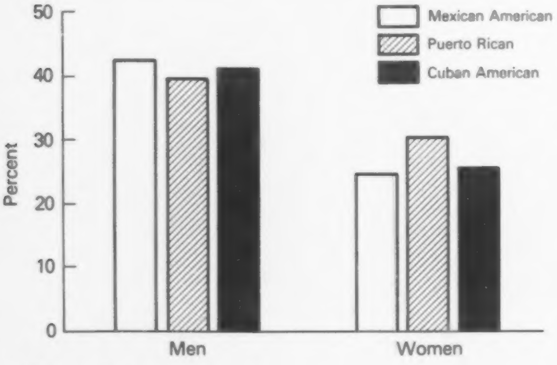
Likewise, the less than adequate response rates in the examined sample, particularly for Cuban Americans and Puerto Ricans, could have biased some of the associations. However, only slight differences were observed in the proportion of men and women who completed the examination cycle as compared to the original sample selected for study. For example, the proportion of men in the examined sample as compared to the original sample (in parentheses) among Mexican Americans 43.9 percent (47.5), Cuban Americans 43.6 percent (44.8), and Puerto Ricans 36.5 percent (39.2) did not vary by more than a few percentage points. Likewise, the percentage of older persons (ages 45–74) among the examined sample did not vary significantly from the original sample for Mexican Americans 37.7 percent (40.3), Cuban Americans 59.4 percent (58.8), or Puerto Ricans 44.2 percent (45.0).

The validation of self-reports of the number of cigarettes smoked per day with plasma cotinine levels for Mexican Americans has recently been published in this Journal.[19] The authors concluded that significant underreporting (22.6 percent) occurred in those Mexican American smokers reporting one to nine cigarettes smoked per day. There were no demographic characteristics that could be identified to characterize the underreporters. A report by Coultas *et al.*[24] among New Mexico Hispanics also found discrepancies between self-reported and validated cigarette smoking. After adjustment for cotinine and carbon monoxide levels, the age-standardized prevalence of current smokers in that study ranged from 30.9 percent (self-reported) to 39.1 percent in males and from 27.1 percent (self-reported) to 33.2 percent in females. Thus, the smoking rates reported by some Hispanics are conservative estimates of the true rates, particularly for the amount smoked.

The inconsistencies between the number of self-reported cigarettes smoked and the results of cotinine concentrations are probably due to underreporting of the quantity of cigarettes smoked per day by a proportion of Mexican American light smokers.[19] However, differences in cotinine metabolism or extremely efficient smoking are alternative explanations that cannot be ruled out by the two studies reported.[19,24]

Results

Figure 1 shows the prevalence rates of cigarette smoking among men and women in the three Hispanic groups. About 40 percent of Hispanic men were current smokers, with age-adjusted rates of 42.5, 39.8, and 41.6 percent in Mexican American, Cuban American, and Puerto Rican men, respectively. With the exception of Puerto Ricans, men were about twice as likely to smoke as women. Puerto Rican women had the highest rates of smoking, at 30.3 percent, which narrowed the sex difference in this ethnic group.



NOTE: Age-adjusted

FIGURE 1—Age-adjusted Prevalence Rates of Current Smoking among Three Hispanic Groups in the HHANES by Sex

The age-specific smoking rates, shown in Table 1, yielded some interesting differences in the three Hispanic populations. Among men, the very high rate of smoking (50.1 percent) in young Cuban men ages 20–34 years was striking. Mexican American men had the highest rates of smoking of the three ethnic groups for ages 35–54 and 55–74 years. Among women, Puerto Ricans were smoking at higher rates than Mexican American or Cuban Americans in the two youngest ages, 20–34 and 35–54 years, with rates of 38.6 and 33.2 percent, respectively. The rates of smoking were markedly lower in the oldest age group in all three Hispanic groups, ranging from a low of 13.7 percent in Puerto Ricans to 19.5 percent in Mexican Americans.

Since comparisons of the Hispanic population with the non-Hispanic White and Black populations of the US are often made, Table 2 compares the age-specific rates, by 10-year age groups, from HHANES with smoking rates in the National Health Interview Survey conducted in 1985. The most noticeable difference was the finding that current smoking rates in the three Hispanic groups were generally higher than the rates observed for non-Hispanic Whites in NHIS, and were only slightly lower than the rates for Blacks. Exceptions were observed among Cuban Americans, where the youngest Cuban American men (ages 25–34) had markedly higher rates than Blacks (57.7 vs 45.2 percent, respectively), and where some of the older Cuban American men had about 10 percent lower rates than Blacks (ages 45–54 and 65–74).

Table 3 presents the percentage of smokers according to the amount smoked (<10, 10–19, and 20+ cigarettes per day) by age, sex, and Hispanic group. In general, the Mexican American population had a much lighter smoking pattern than the Puerto Rican and Cuban American populations. Even if we were to assume that one-fifth of the Mexican Americans who reported smoking <10 cigarettes smoked higher amounts, based on the cotinine validation study,[19] the Mexican Americans would still be lighter smokers than the other two Hispanic groups. About 52 percent of Puerto Rican male smokers and 64 percent of Cuban male smokers consumed 20+ cigarettes a day. These rates are about two times the heavy smoking rates the Mexican American rate of 34 percent rates as well as White male population cited in NHIS (37 percent).

Puerto Rican and Cuban American women smokers were also smoking large amounts of cigarettes. About one-half of Cuban women smokers and about one-third of Puerto Rican women smokers were smoking 20+ cigarettes per day. These rates are about two times those of Mexican American women in HHANES and White women in the NHIS. No marked differences from this pattern were observed for men or women when specific age groups were examined.

Since the brand of cigarette also influences health risk, we examined the usage of various cigarette brands in men and women (Figures 2 and 3). Among Hispanic men, the most popular brands used were Marlboro and Winston, together comprising 66.9, 59.0, and 46.2 percent of most often used brands among Mexican American, Puerto Rican, and Cuban American men, respectively. Contrary to expectation, ethnic brands were not used with great frequency, with the highest proportions observed for Cuban Americans (9.2 percent). Of further note was the large use of Newports by Puerto Rican men (21.0 percent) and of Benson and Hedges by Cuban American men (15.6 percent).

NOTE: Rates are weighted to reflect the values that would occur if the entire Hispanic population had been studied.

A different pattern of cigarette brand usage was seen among women in Figure 3, with Marlboro, Winston, and Salem making up a large percentage of brands used, with combined percentages of 59.7, 46.5, and 47.2 percent usage for Mexican American, Puerto Rican, and Cuban American women, respectively. Puerto Rican women favored Newports (22.0 percent) and Cuban American women favored Benson and Hedges (18.7 percent).

Socioeconomic status has often been cited as an important correlate of cigarette smoking. Table 4 and Figures 4–5 present smoking prevalence rates by income and educational level, respectively. Among men, education was inversely associated with cigarette smoking prevalence rates, for all three Hispanic groups (Figure 4). Among women, no inverse trend was observed. Women with 7–11 years of education tended to have the highest smoking rates for all three Hispanic groups. When income associations were examined in Table 4, the inverse trends were observed for Mexican American and Puerto Rican men only, with those in the lower income group smoking at greater rates than those in the higher income group. For women, similar patterns were observed and more marked for Mexican American and Cuban American groups. With the exception of the education-smoking observation in women, the data generally suggest an inverse association of socioeconomic status and smoking prevalence for both men and women.

Because income and educational levels do not reflect the degree to which the Hispanic population has adopted the US lifestyle, the association of acculturation with current smoking rates was examined for one group of Hispanics, Mexican Americans, in Figure 6. Acculturation was associated with cigarette smoking only among Mexican American women, increasing from 19 percent among Mexican-oriented women to 28 percent among US-oriented women ($p < .05$). For men, there was no clear trend for smoking and acculturation.

Discussion

The adverse health consequences of smoking are now widely known and accepted.[25] The health consequences of smoking that probably have the most public health impact are coronary heart disease, lung cancer, and chronic obstructive pulmonary disease. Excess rates of these diseases have not yet been observed among Hispanics as compared with the White population. If it is true, as the data show, that Hispanic smoking rates are substantially higher than those for Whites, it is likely that future Hispanic rates of these smoking-related diseases will increase. Likewise, if the estimates we have presented are conservative because of self-reporting biases, the findings of high smoking rates in Hispanics are even more dramatic than we have presented.

The HHANES results show a different picture from that reported previously.[3,6,8,26] Hispanic men in all three ethnic groups had significantly higher smoking rates than those of non-Hispanic White men in the US. In addition, Puerto Rican women had significantly higher rates of smoking than other Hispanic women, and somewhat higher rates than those of non-Hispanic White women in younger age groups. The 42.5 percent rates of cigarette smoking in the Mexican American males is quite similar to the estimates reported for men in the

FIGURE 6—Age-adjusted Prevalence Rates of Current Smoking among Mexican American Men and Women by Acculturation Status

late 1970s in California, New Mexico, and Texas.[6,12,26–29][**] Likewise, a recent study by Markides, *et al*,[10] among Mexican Americans in San Antonio showed a 45.8 percent rate of smoking among adults ages 18 and above. Thus, it appears that the overall smoking rates in Mexican American males are not on the decline, in contrast to the trend that has been observed for other White males in this country. Estimates of smoking among Puerto Rican and Cuban American males from the 1979 and 1980 NHIS surveys were also consistent with the 40 percent rate.[5]

Comparisons of Hispanic Americans with Hispanics in the countries of origin are useful in assessing the effect of migration and acculturation on the smoking habits in the US. Data on the smoking rates in Mexico in the 1970s and 1980s have been reviewed by Silva,[30] and show a consistent range of current smoking rates in men between 40 and 45 percent.[31,†] In the same review cigarette smoking rates in women ranged between 15 and 31 percent. Thus, the overall rates for Mexican Americans in the HHANES study are comparable to rates reported in Mexico.

The best survey of Puerto Rican adults came from the Puerto Rican Heart Study, the baseline of which was conducted between 1965–68.[32] In that study, 44 percent of men ages 45–64 years were current smokers, although urban men had significantly lower rates than rural men. Since the HHANES study of Puerto Ricans was conducted in urban areas in the US, the lower rates among the urban men in Puerto Rico are comparable to the smoking rates in the HHANES Puerto Rican men. No data on Puerto Rican women are available for comparison.

Smoking data from Cuba are scarce. Only one report could be found, by Joly and Acosta,[33] who studied Cuban students in grades 10 to 12. Between 40 and 50 percent of students ages 18 and above smoked at least one cigarette per day. The authors speculated that the ultimate prevalence of smoking among Cuban adults is likely to be considerably higher than that found in students 18 years old and over. Again, these reports of high smoking rates are consistent with the 50 percent rates observed in the HHANES Cuban American males ages 20–34 years.

Although several studies have indicated that Hispanics are lighter smokers than other Whites and Blacks,[5,18] our results show that this is the case only for the Mexican American population. We have also seen from the cotinine validation study that these rates are not valid, and about one in five reported light smokers are really heavy smokers.[19] For Puerto Rican males in the New York City area and Cuban American males in the Dade County area, our data show a quite different experience, i.e., the prevalence of heavy smokers (20+ cigarettes per day) is about twice as high as the percentage of light smokers. Our findings are consistent with those of other studies in noting that the brands of cigarettes smoked by these Hispanic groups are high in tar and nicotine.[8,34][††]

The data did not allow us to examine other high-risk smoking behaviors such as inhalation, smoking the cigarette down to the tip, and average time between awakening and smoking first cigarette. However, a recent study by Marin, *et al*,[35] indicated that 49 percent of Mexican Americans (males and females) in their San Francisco sample of current smokers inhaled into the chest; 32 percent burned all the cigarette; and the average wait time to the first cigarette was 257 minutes. Men had slightly worse smoking behavior on these three factors, with 54 percent inhaling, 39 percent burning all the cigarette, and waiting 243 minutes to first cigarette. These findings suggest that there is a serious health risk among smoking Mexican Americans, as well as Cuban Americans and Puerto Ricans.

One factor that may be responsible for the high rates of smoking in the Hispanic populations is the impact of advertising on these populations. It is well recognized that cigarette manufacturers are now targeting the Hispanic and other minority populations with increased expenditures to distribute their message.[7,8,36] Direct advertising to Hispanics is not the only strategy followed by the cigarette industry. Public marketing techniques such as sponsoring meetings, publishing Hispanic directories, and offering monetary contributions to national and community Hispanic organizations to conduct highly visible programs are also used.[7] Given the young median age of the Hispanic population and its potential for tremendous growth over the next several years, it is not likely that the cigarette industry will reduce its efforts in targeting this population. Thus, the public health and medical communities as well as the Hispanic advocacy organizations must recognize this danger and respond to it appropriately.

To deal with the threat of increased smoking behavior in the Hispanic population, it will be also necessary to direct preventive efforts to specific Hispanic sub-populations. Using birth cohort data from HHANES, Escobedo and Remington[37] showed that recent cohorts of Hispanic men have reduced cigarette smoking, while recent cohorts of Hispanic women have made little progress or have actually increased their cigarette smoking. The authors recommended that intervention efforts should be especially targeted toward Cuban American and Puerto Rican women, since the proportion of smokers among successive cohorts of these women appears to have increased markedly. The association of more acculturation with cigarette smoking in women has also been reported in a recent survey of San Francisco Hispanics.[38] The authors note that this may reflect current social norms for smoking in the United States, and should be taken into consideration in the design of prevention and cessation programs for this group. In this era of health promotion and disease prevention, high rates of smoking-related diseases can and should be avoided in the Hispanic population if the proper attention and resources are devoted to prevention.

IX. Acculturation and Marijuana and Cocaine Use: Findings from HHANES 1982–84

HORTENSIA AMARO, PHD, RUPERT WHITAKER, GERALD COFFMAN, MS, AND TIMOTHY HEEREN, PHD

Abstract: We examined the relation between acculturation and illicit drug use among Hispanics in the United States employing data from the 1982–84 Hispanic Health and Nutrition Evaluation Survey (HHANES). Across all Hispanic groups, acculturation into US society, as reflected in English language use, was associated with higher rates of illicit drug use even after sociodemographic variables such as gender, age, income, and education were considered. Significant interactions between language and education indicated that the predominant use of English was more strongly associated with marijuana and cocaine use among Mexican Americans and Puerto Ricans of lower educational attainment than among those of higher educational attainment. Significant interactions between language use and other factors such as sex, marital status, and place of birth were also associated with marijuana and cocaine use. These results suggest that the experience of acculturation, especially as it relates to drug use, is closely tied to the social and economic context in which an individual lives. [*Am J Public Health* 1990; 80(Suppl): 54–60.]

Introduction

Drug use has long been recognized as a major public health problem in the United States,[1] and increasing indicators of serious use in the last two decades have prompted a surge in research to identify patterns and risk factors for drug use in general populations.[2,3] However, these studies have generally not provided reliable epidemiological data on drug use among minorities, especially Hispanics. When data on Hispanics have been reported, most studies have failed to distinguish between Mexican Americans, Puerto Ricans, and Cuban Americans. Failure to specify results by Hispanic subgroup greatly limits the usefulness of such reports for public health efforts since, by the year 2000, Hispanics will be the largest minority group in the United States.[4] While anecdotal, clinical, and some community-based studies suggest that drug use may be a significant problem in Hispanic communities,[5–11] information on general drug use prevalence and the associated risk factors in specific Hispanic groups is essential for prevention and intervention efforts in this population.

One critical experience shared by all Hispanic subgroups is the process of acculturation or culture change resulting from continuous, first hand contact with the United States culture. Since acculturation may involve changes in attitudes, norms, and practices regarding use of illicit drugs, it is important to understand the relation of acculturation to drug use. Psychoactive drug use among Hispanics may be generally associated with increased levels of acculturation into US norms and lifestyle.[12–15] Some research has suggested[16,17] that acculturation may be more strongly associated with the use of some psychoactive substances, such as alcohol, among women than men. Whether acculturation is also more strongly associated with illicit drug use among women than men has not yet been investigated. While these findings on acculturation are suggestive, their generalizability has been limited due to the select and small samples in the reported studies. Most such studies have been limited to one specific Hispanic group or have not identified the group under study. It is also unclear from previous research whether acculturation is associated with increased drug use in all Hispanic groups. Furthermore, because acculturation is associated with improved socioeconomic status,[18] it is unclear to what extent increased drug use is prompted by economic rather than acculturative factors. Moreover, the possible interactions between acculturation and sociodemographic factors, such as sex and other demographic variables, have not yet been systematically investigated.

This paper investigates the extent to which illicit drug use among Mexican American, Puerto Rican, and Cuban American adults is associated with place of birth and language use as indicators of acculturation, and whether this relation differs across gender, age, and socioeconomic status.

Methods

The methods and sampling design used in the Hispanic Health and Nutrition Evaluation Survey (HHANES) are described in detail elsewhere.[19] Briefly, the HHANES is a complex, multistage, stratified, clustered sample of households drawn from three geographic regions (i.e., Southwestern US, Northeastern US, and Dade County, Florida) with the largest national concentrations of Hispanics. Households were screened for eligible respondents, who were asked general information about individuals in the household. The second part of the study involved physical examination and interview at a nearby mobile examination unit. Questions on drug use were included in the Adult Sample Questionnaire Supplement and administered in the interview portion of the study to individuals 12 to 74 years of age.[19]

The present analyses include respondents 20 years of age and older who self-identified as Mexican American in the Southwestern US sample, Puerto Rican in the Northeastern US sample, or Cuban American in the Dade County, Florida sample and who completed the physical examination and interview portions of the study. All respondents were asked questions on marijuana use, but only those younger than 45 years were asked questions about cocaine use. While the HHANES also included questions on use of inhalants and sedatives, data on these substances are not included in this paper due to an insufficient number of users. The participation rates for those approached, aged 20–74, were 58.4 percent among Cuban Americans, 69.2 percent among Puerto Ricans, and 70.2 percent among Mexican Americans. The non-response rate for drug questions did not exceed 1.3 percent. The Mexican American sample includes 3,303 respondents (ages 20–74) who were asked about marijuana use and 2,054 (ages 20–45) who were asked about cocaine use; the Puerto Rican sample, 1,209 and 673 respondents respectively, and the Cuban American sample, 858 and 348 respondents respectively.

NOTE: Author affiliations are listed elsewhere under CONTRIBUTORS.

Questions on drug use were limited to whether the respondent had ever used the drug in question (lifetime use) and the most recent periods of use. Due to the small number of respondents who reported use in the last month and use in the last six months, analyses were conducted only on lifetime and previous year's use (no/yes) of marijuana and cocaine. Information was also obtained on sociodemographic characteristics such as sex, age, marital status, years of education, current employment status, and yearly household income. The HHANES acculturation measure, originally developed for the Mexican American sample, is based on eight items measuring language use, ethnic identification, and birthplace of respondent and respondent's parents. An analysis of the distribution of these items for Puerto Ricans and Cuban Americans revealed that responses to some of these items are highly skewed, rendering the measure inappropriate for general use across all Hispanic groups. To develop an acculturation measure that was equally applicable to all groups, the highly skewed items were deleted and acculturation was measured by: 1) place of birth (coded as within or outside the continental US); and 2) a language index derived from the simple mean of self-ratings on language spoken, language preferred, language written, and language read (each scored English only = 1, mostly English = 2, both English and Spanish = 3, mostly Spanish = 4, Spanish only = 5), and language of interview (coded as English = 1, Spanish = 5).

Statistical Analyses

Age adjusted rates for marijuana and cocaine use: Marijuana and cocaine use rates were calculated for each Hispanic subgroup by gender. Marijuana and cocaine use rates were calculated adjusting for age by a direct standardization method. That is, each of the three Hispanic samples was weighted to reflect the age distribution of the combined weighted sample which reflects the Hispanic population in the United States. Standard errors were calculated accounting for design effects using the RTIFREQS procedure in SAS.[20] These standard errors were used to calculate 95 percent confidence intervals for drug use rates from each of the three Hispanic populations.

Marijuana and cocaine use by place of birth and language use: Marijuana and cocaine use rates by place of birth and language use were calculated. The RTIFREQS procedure in SAS[20] was employed to calculate use rate estimates and their standard errors while accounting for design effects.

Multivariate analysis to assess relationship of acculturation to drug use controlling for socioeconomic factors: To investigate whether indicators of acculturation were independently associated with drug use after the effects of socioeconomic factors were removed, a series of logistic regression analyses were conducted using LOGIST procedure in SAS.[21] The analyses were conducted separately for Mexican Americans and Puerto Ricans; the number of users in the Cuban American sample was too small for multivariate analysis to be meaningful. Use in the year prior to interview (no/yes) was chosen as the dependent variable for the analyses because it was the most recent measure of drug use with a sufficiently large sample to allow multivariate analyses. The sociodemographic variables in the model were: sex (male/female), respondent's age (continuous), yearly family income (<\$20,000/≥\$20,000), currently employed (no/yes), years of education (0–17), and marital status (measured by two dummy variables: separated/divorced/widowed [no/yes] and never married [no/yes], with married as the comparison group). The indicators of acculturation included in the model were: birthplace (continental US/not continental US), and the language index score described previously (range from 1 = Only English to 5 = Only Spanish). Proc LOGIST[1] accounts for sample weights but not design effects;[22] therefore standard errors were corrected for a design effect of 1.5 when calculating p-values and confidence limits.

Multivariate analysis to test interactions between acculturation measures and sociodemographic variables: For each Hispanic group and drug, the model described above served as the basic model to which interaction terms were added and tested one at a time. The interaction terms tested were: language use by birthplace, language use by gender, language use by age, language use by income, language use by education, and language use by marital status. Interactions between language use and birthplace and language use and each of the sociodemographic variables in the model were tested individually.

Test of the final model with all interaction terms: A final model for each drug and Hispanic group—which included all sociodemographic variables, language use, place of birth and all significant interactions as determined in the previous step—was then tested. Language use as a measure of acculturation rather than birthplace was chosen for the interactions because preliminary analyses showed this variable to be most closely associated with drug use.

Results

Sample Characteristics

Table 1 presents selected weighted sample characteristics for each Hispanic group. With the exception of the Puerto Rican sample, which was predominantly female, gender representation was approximately equal. Since drug use patterns have been shown to vary substantially by gender, the overrepresentation of females in the Puerto Rican sample of the HHANES needs to be considered in the interpretation of the findings. The Mexican American and Puerto Rican samples were younger, had a lower yearly family income, and have less formal education than the Cuban American sample. The Puerto Rican sample had a greater proportion of individuals who were unemployed and not currently married compared to the other Hispanic samples. Nearly 60 percent of Mexican Americans were born in the United States mainland, while this was true for only 21 percent of Puerto Ricans and 2 percent of Cuban Americans. Scores on the language use index indicate that Cuban Americans used Spanish more than English, Puerto Ricans were equally divided in language use, and Mexican Americans used English more than Spanish.

Drug Use

Age-adjusted rates for marijuana use: The age-adjusted rates shown in Table 2 indicate that nearly half of Mexican American and Puerto Rican men reported having used marijuana at some point in their lives, while 30.7 percent of Cuban American men reported ever using marijuana. Use of marijuana in the previous year among Hispanic men was reported by 26.6 percent of Puerto Ricans, 22 percent of Mexican Americans, and 12.5 percent of Cuban Americans.

Lifetime use of marijuana was reported by 30.8 percent of Puerto Rican women, but only 19.5 percent of Mexican American women and 11.5 percent of Cuban American women. Compared to lifetime use, use of marijuana in the previous year was reported by fewer women than men in all Hispanic groups. Compared to Mexican American (6.6 per-

Lifetime	6.4 (4.9, 7.9)	21.2 (16.5, 25.9)	7.2 (4.3, 11.0)

cent) and Cuban American women (3.8 percent). Puerto Rican women reported the highest rate of marijuana use (12.5 percent) in the previous year.

Age-adjusted rates for cocaine use: The age-adjusted rates for lifetime cocaine use indicate that 40.6 percent of all Puerto Rican men reported ever using cocaine and 26.9 percent reported using cocaine in the previous year. Among Mexican American men, 19.6 percent reported ever using cocaine and 10.8 percent reported using cocaine in the previous year. One-fifth (20.3 percent) of Cuban American men reported ever using cocaine and 17.1 percent said they used cocaine in the previous year.

Among women, 21.2 percent of all Puerto Rican women reported lifetime use of cocaine, while 6.4 percent of Mexican American and 7.2 percent of Cuban American women reported ever using cocaine. Use of cocaine in the previous year was reported by 13.6 percent of Puerto Rican women but only 2.1 percent of Mexican American and 2.7 percent of Cuban American women.

Marijuana and cocaine use by place of birth and language use: Figures 1 through 4 present the estimates of use and 95 percent confidence intervals (CI) for marijuana and cocaine use in the previous year by birthplace and language index. Use of marijuana and cocaine was reported more often by US-born Hispanic men and women of all groups than by those who were born outside the continental US (see Figures 1 and 2). Overall, the use of marijuana and cocaine use was highest among English-speaking Hispanic men and women than among those who were bilingual, who in turn were generally more likely to report drug use than those who were primarily Spanish-speakers (see Figures 3 and 4). As found in earlier analyses, in comparison to the other Hispanic groups, Puerto Rican men and women reported the highest use of marijuana and cocaine across language categories and birthplace. It should be noted, however, that sample sizes become very small, especially where drug use among Cuban Americans was reported by birthplace and language use, making these estimates highly unstable.

Multivariate Analysis

Table 3 presents odds ratios of socioeconomic and acculturation variables for use of marijuana and cocaine in the previous year among Mexican Americans and Puerto Ricans. The Cuban American sample of users was too small to conduct multivariate analysis. The odds ratios were

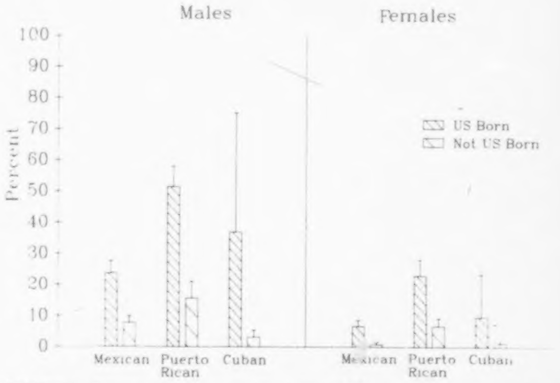

FIGURE 1—Percent of Mexican American, Puerto Rican, and Cuban American males and females who reported using marijuana in the previous year by birthplace

NOTE: Only upper 95 percent confidence limits are presented. The upper and lower limits are equidistant.

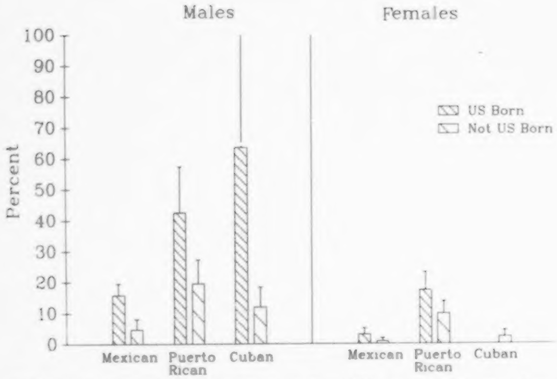

FIGURE 2—Percent of Mexican American, Puerto Rican, and Cuban American males and females who reported using cocaine in the previous year by birthplace
NOTE: Only upper 95 percent confidence limits are presented. The upper and lower limits are equidistant.

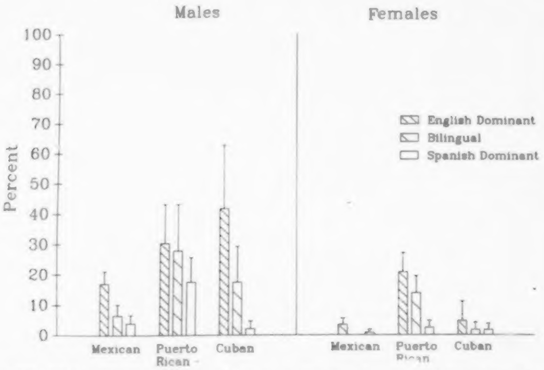

FIGURE 4—Percent of Mexican American, Puerto Rican, and Cuban American males and females who reported using cocaine in the previous year by language use.
NOTE: Only upper 95 percent confidence limits are presented. The upper and lower limits are equidistant.

developed with separate multivariate logistic regressions for each ethnic group/drug combination.

Marijuana Use

Marijuana use and acculturation effects: In both Mexican Americans and Puerto Ricans, language use was significantly associated with marijuana use in the previous year, even after sociodemographic factors were considered. The odds of using marijuana were eight times greater for Mexican Americans and five times greater among Puerto Ricans who were English-speaking than among Spanish-speakers.

Marijuana use and interaction effects: A final model, which included the significant interactions (see Methods) in addition to the basic model presented in Table 3, was tested separately for Mexican Americans ($\chi^2 = 611.84$, df = 12, $p < .0001$) and Puerto Ricans ($\chi^2 = 236.78$, df = 10, $p < .0001$).

Among Mexican Americans, marijuana use in the previous year was often reported by those who were younger ($p < .0001$), not employed ($p < .05$), separated/divorced/widowed ($p < .0002$), and never married ($p < .03$). In addition, significant interactions between language and sex ($p < .02$), language and education ($p < .05$), and language and never-married status ($p < .03$) were found. These interactions suggest that among Mexican Americans, speaking English was *more* strongly associated with a higher rate of marijuana use in the previous year among: women in comparison to men; those who have less formal education in comparison to those with more formal education; and those who were married compared to those who were not married.

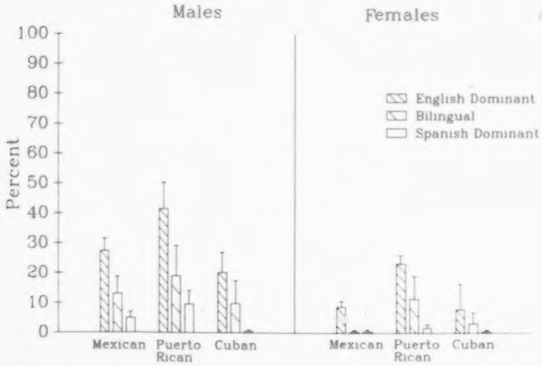

FIGURE 3—Percent of Mexican American, Puerto Rican, and Cuban American males and females who reported using marijuana in the previous year by language use.
NOTE: Only upper 95 percent confidence limits are presented. The upper and lower limits are equidistant.

Among Puerto Ricans, marijuana use in the previous year was most often reported by males ($p < .0001$), young adults ($p < .0001$), individuals with less education ($p < .05$), and those who were predominantly English-speaking ($p < .02$). One marginally significant interaction (language by education, $p < .08$) suggests that use of English among Puerto Ricans was *more* strongly associated with a higher rate of marijuana use in the previous year among those with less education than among those with more education.

Cocaine Use

Cocaine use and acculturation effects: Once sociodemographic variables were taken into account, language use was significantly associated with use of cocaine in the previous year among both Mexican Americans and Puerto Ricans (Table 3). The odds of using cocaine were 25 times greater among Mexican Americans who scored toward the English-dominant end of the language use index than among those who were Spanish-dominant. Among Puerto Ricans, English-speakers were two times more likely than were Spanish-speakers to report cocaine use in the previous year, but the association was weak.

Cocaine use and interaction effects: A final model, which included the basic model presented in Table 3 in addition to all significant interactions, was tested separately for Mexican Americans ($\chi^2 = 257.22$, df = 11, $p < .0001$) and Puerto Ricans ($\chi^2 = 158.29$, df = 12, $p < .0001$).

Among Mexican Americans, cocaine use in the previous year was most likely to be reported by those who were: male ($p < .0001$), young adults ($p < .0001$), less educated ($p < .002$), separated, divorced or widowed ($p < .006$), English-speakers ($p < .0001$), and born in the US ($p < .005$). Two significant interactions between language and birthplace ($p < .001$) and language and education ($p < .001$) suggest that use of English was *more* strongly associated with a higher rate of cocaine use among Mexican Americans who were US-born

p	.0001	.0001	.0001	.0001

than among those who were Mexican-born and among those who had low educational attainment than among those with high educational attainment.

Among Puerto Ricans, cocaine use in the previous year was reported most often by those who were young adults ($p < .0001$), employed ($p < .04$), separated, widowed or divorced ($p < .0001$), never married ($p < .005$), and born in the US mainland ($p < .05$). Significant interactions between language and birthplace ($p < .04$) and language and sex ($p < .005$) suggest that greater use of English was *more* strongly associated with a higher rate of cocaine use among men than among women and among Puerto Ricans born on the island than those born on the US mainland. In addition, a marginally significant interaction between language and education ($p < .07$) suggests that the use of English was *more* strongly associated with cocaine use among Puerto Ricans of low educational attainment than those with higher educational attainment.

Discussion

The results indicate that the rate of marijuana and cocaine use among Hispanics, especially among Puerto Ricans, is higher than that for non-Hispanic Whites.[3] Because previous large-scale studies have not distinguished between the three largest Hispanic groups, the higher rates of drug use among Puerto Ricans may have been diluted by combining them with other Hispanics, who have drug use rates similar to those reported for non-Hispanic Whites.

It is possible that the higher rates of drug use among Puerto Ricans compared to other Hispanic groups reflect regional patterns of drug use. Some support for this interpretation is found in the data from the National Household Survey,[3] in which prevalence of lifetime and previous year marijuana and cocaine use was highest among those living in the Northeast region of the US. However, the lifetime and previous year rates for cocaine use among Puerto Ricans in the HHANES were higher than those reported in the general population of the US Northeast corridor. For example, data from the National Household Survey indicate that 8 percent of women, and 18 percent of men in the general Northeast population have used cocaine at some point in their lives. These rates were much lower than those estimated for Puerto Ricans from the HHANES (21.2 percent and 40.6 percent, respectively). Comparisons of estimates for use of cocaine in the previous year follow a similar pattern, suggesting that use of cocaine cannot be attributed solely to the geographic location.

The results also indicate that acculturation into US society, as reflected by language use, was accompanied by a higher prevalence of illicit drug use. This relationship holds true even when sociodemographic variables are taken into account. Yet, the relative strength of the association between acculturation measures and drug use varied across Hispanic subgroup and by drug. While the cross-sectional design of this study does not allow for an analysis of the process of acculturation, the results lead us to believe that it is important to develop research to further investigate the nature of the acculturation process among Hispanic subgroups and its relationships to drug use.

One possible factor which influences the impact of acculturation on drug use is the social context of drug use in the native country. For example, it is possible that drug availability and norms in Puerto Rico are closer to those in the US mainland than to those in Mexico or Cuba. This interpretation is supported by previous reports of drug use in Puerto Rico.[23,24] Thus, in order to better understand the factors which impact drug use among Hispanics living in the US mainland, research is needed on social norms and drug use practices in the countries from which Hispanics originate.

The results also suggest that the relation of acculturation to drug use differs across education levels. Acculturation, as measured by language use, had the strongest relation to drug use among those who were least educated. Mexican Americans and Puerto Ricans who were highly acculturated, but had not enjoyed access to educational resources of American society, were most likely to report marijuana and cocaine use. Similar findings indicating that high acculturation is associated with alcohol use among poor Hispanic men have been reported in the literature.[17,25,26] Acculturation, when accompanied by poverty and/or lack of access to education, may resemble what Berry termed "marginalization."[27] In this type of acculturation, an individual loses essential features of his/her culture and at the same time has not entered the larger society. This type of acculturation results in feelings of alienation and loss of identity, is highly stressful, and places an individual at high risk for poor mental health outcomes.[27]

Our findings also suggest that, in some cases, the relationship of acculturation to drug use varies by sex. Once socioeconomic factors were considered, the gender gap in marijuana use was relatively small among Mexican Americans who speak primarily Spanish. This contrasts with the rates of drug use among those who were predominantly English-speaking, for whom the rates were much higher among men than among women. Yet, the relative difference in drug use between Spanish- and English-speakers was larger among women than men. This finding is consistent with reports in the alcohol literature, which suggest that acculturation is more strongly associated with alcohol use among Mexican American women than among Mexican American men.[16,17] However, among Puerto Ricans, acculturation was more strongly associated with cocaine use among men than among women. The findings indicating that acculturation is differentially associated with drug use across educational levels and gender leads us to suspect that acculturation, as it relates to drug use, is integrally affected by the social and economic context in which an individual becomes socialized and lives. The impact of gender roles and educational attainment on drug use and their relation to acculturation among Hispanics deserves empirical investigation.

HHANES, although the first large scale survey to provide information on drug use among various Hispanic groups in the US, is limited in several ways. First, the measures of acculturation used in the HHANES were developed for Mexican Americans and not for Puerto Ricans and Cuban Americans. Second, measures of drug use employed in the HHANES do not allow assessment of the degree or context of drug use or the impact of drug use on functioning. Third, the HHANES employed self-reported measures of drug use, which are vulnerable to multiple threats to validity.[28] Respondents tend to underreport socially undesirable behaviors. What is deemed undesirable behavior may differ among women and men and among those who are not acculturated compared to those who are highly acculturated. If gender roles and culture determine norms regarding drug use, then the validity of self-reported drug use may also vary by these factors. Even with these limitations, the findings have important implications for the study of drug use among Hispanics because they provide evidence of a relationship between acculturation and illicit drug use. The findings also underscore the need for a better understanding of the process of acculturation among Hispanics and other immigrant groups.

The present findings also indicate the need for further studies of drug use among Hispanics, especially Puerto Ricans on the mainland and on the island. Because of the close political, economic, and legal ties between Puerto Rico and the United States mainland, and because of the continuous migration to and from Puerto Rico, drug availability and norms of drug use in the continental US may have a direct effect on drug use among Puerto Ricans living on the island. Yet, Puerto Rico is not usually included in national studies of drug use, leaving a critical gap in knowledge about a substantial Hispanic population in the US. Further, public education campaigns and prevention efforts to reduce initiation into drug use have not typically included Puerto Ricans on the island. Policy initiatives are needed to develop and implement prevention programs aimed at the Puerto Rican population on both the island and in the mainland. Such initiatives should include ongoing mechanisms for gathering information on drug use among Puerto Ricans.

ACKNOWLEDGMENTS

This investigation was funded by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC.

X. Generational Differences in Perinatal Health among the Mexican American Population: Findings from HHANES 1982–84

SYLVIA GUENDELMAN, DSW, JEFFREY B. GOULD, MD, MPH, MARK HUDES, PHD, AND BRENDA ESKENAZI, PHD

Abstract: Data from the Hispanic Health and Nutrition Examination Survey (HHANES) were used to examine a profile of social, medical, and behavioral characteristics associated with low birthweight (LBW) and miscarriages in first and second generation Hispanics of Mexican descent. The percentage of LBW was 5.3 and of miscarriages was 12.7. LBW rates were higher for second generation primipara and multipara compared with first generation women. Using multivariate logistic regression techniques and adjusting for complex design effects, generation was found to be a significant predictor of LBW but not of miscarriages. The findings support existing evidence that a Mexican cultural orientation protects first generation, Mexico-born women against a risk for LBW. However, the findings do not show significant effects of generation on miscarriages, suggesting that cultural effects are not consistent for all pregnancy outcomes. Furthermore, we suggest that the higher rates of LBW in second generation women are not due to a higher rate of miscarriages as has been hypothesized. [*Am J Public Health* 1990; 80(Suppl):61–65.]

Introduction

The Mexican-origin population in the United States has been growing sharply since 1970, largely as a result of high fertility rates and immigration. Despite the high birth rates of Hispanic women, little is known about their perinatal outcomes and their associated risk factors. Existing evidence, mainly derived from birth and death certificates, suggests that Mexican-origin women have birth outcomes similar to those of White non-Hispanic populations.[1–9]

Recent findings also suggest that birth outcomes are more favorable among first generation women born in Mexico than among second or successive generations of US-born women of Mexican descent. According to a 1985 nationwide study, only 5.0 percent of the infants of Mexico-born mothers were of low weight, compared to 6.3 percent of infants of US-born Mexican origin mothers and 5.7 percent of white non-Hispanic mothers.[7] Similar differential rates by birthplace have been found in California, the state with the largest concentration of Mexican descendants,[1] and most recently by Scribner and Dwyer[10] in a study of the Hispanic Health and Nutrition Examination Survey (HHANES).

The lower rates of low birthweight (LBW) of first generation mothers is intriguing and difficult to explain according to evidence derived from birth certificates.[1,4–7] Compared to US-born mothers of Mexican descent, foreign-born, first generation women have a lower socioeconomic status, a higher percentage of women over 35 years of age, and less adequate prenatal care.[2–4] On the basis of these risks, one would expect first generation mothers to have an increased risk of LBW. Recent evidence from the HHANES challenges this assumption. According to Scribner and Dwyer women with a Mexican cultural orientation have a reduced risk of LBW, even after controlling for sociodemographic characteristics and smoking.[10] A Mexican orientation serves as a marker for a lifestyle that is protective against the negative influences on pregnancy outcomes.[10,11]

A few other studies have suggested that the lower LBW rate in Mexico-born women may be related to a high rate of miscarriages which eliminate weaker fetuses.[12,13] Approximately 10 percent to 15 percent of pregnancies identified by conventional criteria end in clinically recognizable spontaneous abortions.[14] Miscarriage/stillbirth rates for Mexican American farmworkers range from 24 percent to 31 percent, depending on the target population and method of ascertainment.[15,16]

In this study, we use the HHANES data base to examine the acculturation and miscarriage hypotheses regarding more favorable LBW rates in Mexico-born compared with US-born women of Mexican origin. For this purpose we first explore a wide array of social, behavioral, and medical variables associated with LBW and miscarriages in first and second generation women of Mexican descent. We subsequently investigate the effects of generation on LBW, controlling for social, behavioral, and medical factors in separate predictive models for primipara and multipara. The use of separate models is based on findings by Eisner, *et al*,[17] indicating that multipara have a lower percent LBW than primipara and different factors predict LBW in each group. Finally, controlling for the other maternal characteristics in a multivariate regression model, we examine whether generational status also has an effect on miscarriages.

Methods

Sample

Data were obtained from the Medical History section of the HHANES which is a health survey conducted in 1982–84 of three Hispanic sub-populations (Mexican American, Puerto Rican, Cuban American)[18] living in selected areas of the United States.[18] The survey contains information on approximately 8,500 Mexican Americans residing in the southwestern US. Representatives were selected using a multistage, stratified area probability sample of households and residential clusters. All adult women of Mexican birth or origin, were initially included in this study if they were interviewed in the household and examined in a mobile examination unit and were between the ages of 16 and 55. We excluded women over age 55 due to concerns regarding recall accuracy. Out of 1,518 participants, 128 (8.4 percent) were excluded due to missing values of LBW, miscarriages, and/or generation which are the key variables of interest. Thus the final analytic sample consisted of 1,390 respondents.

Definition of Variables and Data Analysis Technique

Our two outcome variables are a history of LBW and of miscarriages (0 = no; 1 = yes) derived from the following HHANES questions:

- For *multipara*, "How many of your children (who were born alive) weighed less than 5½ pounds (2,500

Note: Author affiliations are listed elsewhere under CONTRIBUTORS.

grams) at birth?" and "What is the total number of live births you have had?"

- For *primipara*, "Did this (the only) child weigh less than 5½ pounds (2,500 grams) at birth?"
- Other questions asked of *all women* were "What is the total number of miscarriages you have had?" and "How many times have you been pregnant?"

Generation, which is determined by the birthplace of the subjects, was selected as the primary independent variable. To allow for sufficient sample size, the original three-generation coding given in the data tape (first generation born in Mexico; second generation not born in Mexico, one or both parents born in Mexico; third or higher generation, neither parent born in Mexico) was collapsed into two groups: 1) subjects born in Mexico whose parents were born outside the US, and 2) subjects born in the US who had at least one parent born in Mexico or of Mexican descent.

Other social, behavioral, and medical variables were initially screened if they have been reported in the literature as significantly related to birthweight or miscarriages in non-Hispanic populations.[19,14] Only those variables that were at least moderately associated ($p \le .20$) with LBW in pairwise analyses and/or with miscarriages in separate pairwise analyses (adjusting for number of live births and number of pregnancies, respectively) were included for further study.

The *social variables* considered in the predictive models for LBW and miscarriages are: 1) Medicaid coverage in the last 12 months prior to the interview; 2) highest grade of regular school completed; 3) family income which is the combined income obtained in the last 12 months from jobs, public assistance, rents, interests or other sources; 4) marital status which refers to whether a spouse is living in the home; and 5) age in years at the time of the interview.

The *behavioral factors* are: 1) current drinker status determined by asking of non-abstainers whether they have had a drink in the last 28 days; 2) current smoker status determined by the question "Do you currently smoke cigarettes?"; and 3) interval, in years, since the last Pap smear test, recoded into four ordinal categories ranging from last two weeks to never.

Medical factors include: 1) self-reported physician-diagnosed blood pressure or hypertension; 2) Quetelet index, i.e., a body mass index based on self-reported weight at age 25 and height (weight/height^2). On the basis of the pairwise analyses described above, three additional variables were included in the model for miscarriages, namely: self-reported physician diagnosed diabetes, heart problems, and self-perceived health status ranging from very good to poor.

Differences between the two generational groups for each independent and outcome variable were examined by performing Student's two sample t-tests for the continuous variables and chi-square tests for the categorical variables. Since the HHANES is a multistage, stratified probability sample of clusters of persons in area-based segments,[18] estimates were weighted using the "examined weights" and complex design effects were taken into account using the Super Carp program.[20] To facilitate presentation, only the weighted values and statistics are presented in the generational profile in Table 1.

Logistic regression was used (SAS Logist procedure)[21] to examine the effects of generation on each outcome variable controlling for the social, medical, and behavioral factors studied. Only cases which had complete information on all these variables were included in the analyses (n = 1,078). We ran simultaneous logistic regressions for all women and then separate models for primipara and multipara. From these results we estimated odds ratios and their 95 percent confidence intervals. For continuous or ordinal predictors, standardized odds ratios are estimated. These are presented in Tables 2–5. To check whether the statistical significance of some variables might be affected by collinearity with other variables, the simultaneous logistic procedure was followed

TABLE 1—Maternal Characteristics by Generation for Hispanic Women, HHANES 1982–84

**p values represent the significance level for the first and second generation comparison in the weighted analysis.

up with a backwards stepwise regression.[21] Data in the models were weighted according to the scaled weighting procedure proposed by the National Center for Health Statistics, where the sum of the weights is equal to the observed sample size.[22] The results on Tables 2–5 were also examined adjusting for complex design effects using the estimated average design effect of 1.5 as described by Delgado, et al.[23]

Results

Generational Profiles of Maternal Characteristics

The two generational groups were similar with respect to age at interview (34.1 years for the first and 34.3 years for the second) and the proportion of primiparous women (19.7 percent in the first and 20.8 percent in the second). The findings in Table 1 indicate that a variety of significant changes take place between the first and second generation or beyond. Second generation women have a significantly higher educational attainment than first generation women. On the average they have 3½ more years of formal schooling. Family income is also significantly higher in the second generation despite the fact that, compared with the first generation, there are more women living without a spouse at home. From a behavioral standpoint, far more second generation women are smokers and drinkers than first generation women. However, significantly fewer second generation women have never had a Pap smear compared with those in the first. No significant differences in high blood pressure or Quetelet index were found between the two generations, but second generation women had significantly higher proportions of physician-diagnosed diabetes and heart problems. Despite reporting more medical problems, second generation women perceived their health status significantly better than first generation women.

Generational Effects on Low Birthweight

The percentage of low birthweight out of the total live births for Mexican origin mothers is 5.3 (S.E. = 0.04). This estimate is similar to the rates based on birth certificate data reported by Williams[1] (5.3 percent) and Ventura[5] (5.6 percent) and higher than those reported by Scribner and Dwyer[10] (4.8 percent) using an HHANES sample of older women up to age 74. Similar to Scribner and Dwyer, we found that LBW rates differ significantly for the two generational groups. Out of the total live births for the first generation 3.9 percent (S.E. = 0.7) are of LBW, whereas out of the total live births for the second generation, 6.1 percent (S.E. = 0.7) are of LBW. The generational effects on LBW are significant, even after adjusting, in a logistic regression model, for the social, behavioral and medical characteristics. The risk of LBW is 1.73 times higher (95% CI = 1.11, 2.71) in the second generation compared with the first (Table 2). This result remains significant even after adjusting for complex design effects.

We examined the generational differences in birthweight outcomes in the two parity groups and found that, in the first generation, the LBW rate was 6.3 percent (S.E. = 1.8) in primipara and 3.8 percent (S.E. = 0.05) in multipara. In the second generation, primipara also had higher rates: 9.7 percent (S.E. = 2.4) compared with 5.9 percent (S.E. = 0.06) in multipara. These estimates indicate that although the percentage of LBW increases in the second generation, in both generations primipara have LBW rates that are almost 1.5 times higher than multipara.

TABLE 2—Adjusted Odds Ratios[+] for Low Birthweight (n = 1078)

Variables	Adjusted Odds Ratios[*]	95% CI
Generation (0 = first, 1 = second or beyond)	1.73	1.11, 2.71

[+] Logistic regression analysis techniques were used to obtain the adjusted odds ratios.

[*] For the continuous and ordinal variables, standardized odds ratios are presented.

[**] To evaluate the Quetelet index (a nominal variable with 3 categories), a χ^2 test statistic with 2 D.F. was obtained from the difference of two log likelihood functions and was found to be not statistically significant.

As shown in Table 3, we found that after adjusting for the potential confounders included in the logistic regression model, the risk of LBW is approximately four times higher for second than first generation primiparous women (OR 4.08; 95% CI = 0.81, 20.45). The risk factor, however, was not statistically significant at the p = .05 level, possibly due to small sample size. The risk for LBW is five times higher for primiparous women with a physician-diagnosed history of high blood pressure (OR 5.07; 95% CI = 1.59, 16.20) and it almost doubles when the interval since last Pap smear is greater than one standard deviation from the mean (OR 1.87; 95% CI = 1.09, 3.20). After adjusting for complex design effects, the only significant predictor that remained was blood pressure.

The effect of generation on LBW was significant for multiparous women. The findings in Table 4 show that the risk of LBW is almost double for second generation women (OR 1.69; 95% CI = 1.05, 2.84) and for current smokers (OR 1.79; 95% CI = 1.16, 2.76). Smoking remained a significant predictor even after adjusting for complex design effects. Results similar to those obtained with the logistic regression techniques were obtained when doing backwards stepwise regressions for primipara and multipara.

Generational Effects on Miscarriages

The percentage of miscarriages out of the total number of pregnancies for Mexican origin mothers is 12.7 percent (S.E. = 0.59). This rate falls within the expected range for spontaneous abortions in the mainstream population.[14] Furthermore, the rates for the two generational groups are not significantly different. Out of the total number of pregnancies for the first generation, 13.1 percent (S.E. = 0.99) have had miscarriages. For the second generation the percentage of miscarriages is 12. 5 percent (S.E. = 0.60).

Using logistic regression, we examined whether generation becomes a significant predictor of miscarriages after adjusting for the social, behavioral and medical factors listed in Table 5. Generation was not a significant predictor of miscarriages (OR 0.81; 95% CI = 0.57, 1.15). The adjusted odds ratios reported in Table 5 indicate that miscarriages increase 1.25 times with every increase in one standard deviation in education (95% CI = 1.04, 1.51); it increases 1.47 times (95% CI = 1.79, 1.22) with every decrease in one standard deviation in age and 1.43 times among women without a spouse living at home (95% CI = 2.13, 0.97). Education and age remained significant after adjusting for complex design effects.

Since Scribner and Dwyer[10] reported that generation was not as strong a predictor of pregnancy outcome as acculturation, we examined the role of acculturation in predicting miscarriages. Like Scribner and Dwyer, we looked at the effect of the acculturation index with and without including generation and found that it was not a significant predictor of miscarriages.

TABLE 4—Adjusted Odds Ratios[+] for Low Birthweight among Multiparous Women (n = 892)

Nor was generation a significant predictor of miscarriages when logistic models were constructed separately for primipara and multipara (primipara: OR 0.76; 95% CI = 0.31, 1.87; multipara: OR 0.91; 95% CI = 0.62, 1.34). However, for primipara, an older age at interview (OR 1.74; 95% CI = 1.17, 2.57) and Medicaid coverage (OR 3.30 95% CI = .93; 11.69) was positively associated with miscarriages, whereas in multipara age and socioeconomic factors were inversely associated with miscarriages (age OR 0.64; 95% CI = 0.52, 0.78; income OR 1.17; 95% CI = 0.97, 1.42; education OR 1.22; 95% CI = 1.00, 1.49).

Discussion

The findings from this study show that for the Mexican origin population in the United States the percentage of LBW was 5.3 and the percentage of miscarriages was 12.7. Whereas the incidence of LBW in this population is lower than that for the general population, the rate of miscarriages seems similar to what is expected for the mainstream population.[5,8,14]

Mexican Americans are a heterogeneous group and our analysis demonstrates that wide variations are found according to generation and parity. US-born Mexican Americans are at 60 percent higher risk for LBW than Mexico-born women. Furthermore, the rate of LBW among US-born primipara at 9.7 percent begins to approximate that of the Black population.[19]

The findings, based on a rich array of variables, further demonstrate that across generations, significant changes take place in certain bio-social-behavioral characteristics of mothers which are associated with pregnancy outcomes (Table 1). While second generation Mexican American women show a higher educational and income status and more use of health care relative to their first generation counterparts, certain behavioral characteristics such as smoking and drinking behaviors actually deteriorate in the second generation. The second generation also has higher rates of physician-diagnosed diabetes and heart problems. However, this could be a result of improved access to care rather than to poor health status.

Our multivariate models indicate that generation is a significant predictor of LBW but not of miscarriages. This evidence points to two important findings: first, even after controlling for other factors, US-born Mexican origin women of the second generation or beyond have a higher likelihood of giving birth to LBW infants; and second, these patterns are not consistent for all pregnancy outcomes.

According to the acculturation model, the behaviors or lifestyles that protect women against adverse pregnancy outcomes are associated with a Mexican cultural orientation which predates pregnancy. If this were the case, we would have expected that generation (as a proxy for acculturation) would have been a significant predictor, not only of LBW but also of miscarriages. Evidence from this study does not support this conclusion. The findings show no significant effects of generation or the acculturation index on miscarriages. Rather than cultural factors, the results suggest that socioeconomic, genetic, and unaccounted medical factors are better predictors of miscarriages in Latinas.

Furthermore, the findings do not support the hypothesis that increased fetal losses explain the more favorable LBW outcomes in first generation Mexican-Americans.[12,13] The 13.1 percent miscarriage rate in the first generation was very similar to the 12.5 percent found in the second generation.

However, the possibility of reporting bias cannot be discounted in this study. Underreporting miscarriages among first generation women could occur as a result of less education which leads to less body awareness or less likelihood of recognition of miscarriages. Furthermore, compared with US-born, Mexico-born women are more likely to seek prenatal care late or none at all,[5] and thus are less likely to receive a medical diagnosis if miscarriages occur. Conversely, because induced abortion in Mexico is illegal, Mexico-born women could be misreporting induced abortion as miscarriages to make it more acceptable.[24] The possibility of measurement error also arises given the potential ambiguity concerning what events actually constitute a miscarriage. We suspect that miscarriages may be more prone to reporting bias than LBW, particularly among less educated women. Hence, further studies are needed to confirm the validity of the fetal loss hypothesis.

Because the HHANES is a cross-sectional, retrospective survey, variables do not necessarily measure the conditions or behaviors at the time of birth, hence possibly washing away some of the effects. In this study, the recall bias was as long as 40 years and no attempts at verifying the accuracy of the miscarriage or LBW information given to the mother at the time of delivery were made in the HHANES. Nevertheless, some of the traditional risk factors e.g. smoking for LBW and e.g. age for miscarriages are corroborated using the HHANES data. Furthermore, the results of LBW are consistent with those found by Williams, *et al*,[1] in California. The latter found that the lower rates of LBW among Mexico-born compared with US-born women of Mexican origin could not be the result of systematic underreporting by Mexican women.

In conclusion, the findings from the HHANES suggest that cultural explanations of differential pregnancy outcomes in women of Mexican origin must be restricted to LBW. The evidence strongly argues for the need to include generation as a risk factor when doing studies of LBW in Mexican-Americans. Further studies are also needed to assess the extent to which prematurity or intrauterine growth retardation determine pregnancy outcomes in each generation. This is a question that cannot be addressed in the HHANES.

ACKNOWLEDGMENTS

This investigation was funded by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC.

The authors would like to thank Olivia Carter-Pokras, Katherine Flegal, and Peter Gerdsen at NCHS for their helpful comments. Special thanks are also extended to Mary Maddox-Gonzalez, MD, MPH, and Jose Enz, MD, MPH, for their help in the early stages of the study.

XI. The Prevalence of Total Tooth Loss, Dental Caries, and Periodontal Disease among Mexican Americans, Cuban Americans, and Puerto Ricans: Findings from HHANES 1982–1984

AMID I. ISMAIL, BDS, MPH, DRPH, AND SUSAN M. SZPUNAR, RDH, DRPH

Abstract: This paper describes the prevalence of total tooth loss, dental caries, and periodontal disease in 2,226 Puerto Ricans, 1,192 Cuban Americans, and 5,983 Mexican Americans, ages five to 74 years, who were examined during the 1982–84 Hispanic Health and Nutrition Examination Survey (HHANES). The prevalence of total tooth loss was 2.60, 6.10, and 2.80 percent among Mexican Americans, Cuban Americans, and Puerto Ricans, respectively. After adjusting for the confounding effects of age, sex, income, and education status, no statistically significant differences were found in the mean number of decayed teeth among the three groups of Hispanics. Puerto Rican children had an average of 2.09 filled teeth compared with an average of 1.39 and 1.43 filled teeth for Mexican Americans and Cuban Americans, respectively. In adults, Puerto Ricans and Cuban Americans had at least 40 percent higher mean number of filled teeth than Mexican Americans. Cuban American and Puerto Rican adults had about twice as many missing teeth as Mexican Americans. The pit-and-fissure tooth surfaces in children accounted for the majority of sites affected by caries.

All Hispanics had a higher prevalence of gingivitis than American adults as estimated during the 1985–86 National Institute of Dental Research (NIDR) survey of American adults. Puerto Ricans had the highest level of periodontal disease and the highest Debris Index scores among the Hispanic groups. [*Am J Public Health* 1990; 80(Suppl):66–70.]

Introduction

Dental public health practice in the United States is now facing new challenges. In addition to the political and economic changes that have affected public health programs in the last decade, there has been a significant increase in the numbers of the elderly and minorities, such as Hispanics.[1,2] As the proportion of minorities in the US increases, data on their oral health status will be needed to plan the treatment and preventive services required to meet their health needs.

Data from recent national surveys show a disturbing pattern of untreated dental caries in Blacks and Mexican Americans.[3–5] In the 1985–86 national survey conducted by the National Institute of Dental Research (NIDR),[3] Blacks had a higher mean number of decayed tooth surfaces than White non-Hispanics in all age groups between 18–19 and 60–64 years of age. The differences in mean numbers of decayed tooth surfaces between White and Black Americans ranged from 66 percent in adults 30–34 years of age to 419 percent in those 60–64 years of age. Despite the higher level of decayed teeth in Blacks, their mean number of permanent decayed and filled tooth surfaces (DFS) was lower than that of Whites, because of the lower mean number of filled teeth in Blacks. These differences between Black and White adults were similar to those found during the first National Health and Nutrition Examination Survey (NHANES I) conducted between 1971 and 1974,[6] where Blacks had a 93 percent higher mean number of decayed teeth than non-Hispanic Whites. In 1971–74, the latter had three times higher mean numbers of filled teeth than Blacks.

Information about the oral health status of Puerto Ricans, Cuban Americans, Mexican Americans, and other minorities in the United States is sparse. In a 1972–73 survey in New York City by Nikias and co-workers,[7] Puerto Ricans had a lower number of filled teeth than non-Hispanic Whites, but the mean number of filled teeth of Puerto Ricans was not different from that of Blacks. Non-Hispanic White New Yorkers had a lower mean number of decayed teeth than Blacks and Puerto Ricans. Puerto Ricans also had a higher level of gingival inflammation than non-Hispanic Whites and Blacks. Other geographically limited surveys of dental caries prevalence of Puerto Ricans and other Hispanics have reported similar findings.[8,9]

As described elsewhere in this supplement,[10] the National Center for Health Statistics (NCHS) responded to the lack of information on the health and nutritional status of Hispanics in the United States by conducting the Hispanic Health and Nutrition Examination Survey (HHANES) between 1982 and 1984. Previous reports described the prevalence of dental caries and periodontal disease of Mexican Americans living in five Southwestern states.[4,5] Dental data on Puerto Ricans and Cuban Americans became available for analysis in 1987. This report describes the prevalence of total tooth loss, dental caries, periodontal disease, and oral hygiene status in Cuban American and Puerto Rican children and adults, ages five years or older. Because of the small number of Cuban Americans and Puerto Ricans examined during HHANES compared with Mexican Americans, the age groups used in previous reports could not be used in this analysis.[4,5] Therefore, a re-analysis of the Mexican Americans' dental data was carried out in order to provide a comparison group to both Cuban Americans and Puerto Ricans.

Methods

A description of the HHANES sample design and data collected is presented elsewhere in this supplement.[10] Previous reports have summarized the criteria used during HHANES to measure the prevalence of dental caries, periodontal disease, and oral hygiene status.[4,5]

In this report, data will be presented for 5,983 Mexican Americans, 1,192 Cuban Americans, and 2,226 Puerto Ricans between the ages of five and 74 years with dental data. All those who identified themselves as Mexican Americans in Arizona, California, Colorado, New Mexico, and Texas; as Puerto Ricans in the New York City area; and as Cuban Americans in Dade County, Florida, were included in this study. Out of those medically examined, only 2.97, 1.25, and 2.36 percent of Mexican Americans, Cuban Americans, and Puerto Ricans, respectively, between six months through 74

Note: Author affiliations are listed elsewhere under CONTRIBUTORS.

years of age, did not receive a dental examination. Only the dental status of the permanent teeth is described in this paper.

All means, percentages, and regression coefficients presented were computed using sampling weights as described by Delgado and co-workers[10] and Landis, *et al.*[11] Also, adjustment for clustering effects was carried out when standard errors of the means, percentages, and regression coefficients were computed using the design effects provided by the NCHS and published in Public Use Data Tape Documentation (Dental Health, Tape number 6505). The dental variables used in the analysis were: total tooth loss; number of decayed, filled, and missing teeth (and tooth surfaces) for each individual; the Periodontal Index (PI) scores,[12] and periodontal classification based upon the PI score (no periodontal disease, gingivitis only, periodontal pockets) and Debris Index (DI) and Calculus Index (CI) scores for those with at least one tooth in their mouth.[13]

Differences in the dental status among the three Hispanics groups were considered present only if they remained after adjusting for the confounding effects of age, sex, income, and education. Multiple linear regression analysis was used during adjustment when continuous variables were compared, and logistic regression analysis was used when a dichotomous variable was the dependent variable. This approach was used because of the differences among the three groups in age, income, and education levels: the Puerto Rican sample included a higher percentage of individuals with an average family income below $10,000 than the other groups and about 43 percent of the Puerto Ricans examined were below the poverty line (computed by dividing the total household income by the total income determined necessary [from federal guidelines] to maintain a family on a nutritionally adequate diet; a ratio of 1.0 was considered as the poverty line) compared with about 29 and 22 percent of the Mexican and Cuban Americans, respectively.

All analyses were carried out using OSIRIS. IV, supported by the Institute for Survey Research, University of Michigan.

Results

Total Tooth Loss

Cuban Americans had a significantly higher prevalence of total tooth loss than both Mexican Americans and Puerto Ricans (Table 1). When the confounding effects of age, sex, income, and education status were accounted for using a logistic regression model, however, no significant differences in the prevalence of total loss among the three groups were found (data available on request to authors).

TABLE 1—Number of Mexican Americans, Cuban Americans, and Puerto Ricans, Ages Five through 74 Years, by Edentulous Status and Age, HHANES, 1982–84

	Mexican Americans		Cuban Americans		Puerto Ricans	
Age (years)	N*	%E**	N	%E	N	%E
5–17	2,528	.00	294	0.00	939	.00
18–44	2,252	.30	390	1.30	799	1.40
45–74	1,203	14.40	508	14.90	528	12.90
All Ages	5,983	2.60	1,192	6.10	2,266	2.80

*N = Total Number of Hispanics ages 5 through 74 years.

**%E = Percent edentulous (with total tooth loss) and, henceforth, were not included in Tables describing the status of individuals with teeth.

Dental Caries Prevalence

Among dentate Hispanics, ages five through 44 years, Puerto Ricans had a significantly higher mean number of decayed teeth than Cuban Americans (Table 2), but not Mexican Americans; this difference disappeared, however, when age, sex, income, and education status were accounted for using a multiple linear regression model (data available on request to authors). In older Hispanics, Mexican Americans had a significantly higher mean number of decayed teeth than either Cuban Americans or Puerto Ricans but, again the difference disappeared after accounting for the confounding effects of age, sex, income, and education status, using a multiple linear regression model (Table 3). Hispanic adults had significantly higher mean number of decayed teeth than Hispanic children.

Puerto Rican children had an average of 2.09 filled teeth compared with an average of 1.39 and 1.43 filled teeth for Mexican American and Cuban American children, respectively, a difference which remained statistically significant in the regression analysis (data available on request to authors). In adults, Puerto Ricans and Cuban Americans had at least 40 percent higher mean number of filled teeth than Mexican Americans (Table 2). In Hispanics older than 45 years, the mean number of filled teeth of Cuban Americans and Puerto Ricans was significantly higher in the regression analysis than that of Mexican Americans, with Cuban Americans having the highest mean number of filled teeth of the three groups.

Cuban American and Puerto Rican adults had approximately two times more missing teeth than Mexican Americans (Table 2). This difference did not disappear after accounting for the previously described confounding variables. Mexican American adults (18–74 years of age) who were

*Standard errors were adjusted for clustering effects (see Methods section). Confidence intervals were computed with adjustment for design effects as described in the Delgado, *et al.*, paper.[10]

below the poverty line had a significantly higher mean number of decayed teeth and a lower mean number of filled teeth than those above the poverty line. Differences in the mean numbers of decayed and filled teeth, by age groups, between Puerto Ricans and Cuban Americans below and above the poverty line were inconsistent because of small sample sizes.

Table 4 presents the distribution of dental caries by the type of tooth surface affected in Hispanic children. Puerto Ricans ages five to 17 years had significantly higher DFS (decayed and filled tooth surfaces) scores on occlusal surfaces than Mexican and Cuban Americans. In the buccal and lingual tooth surfaces of posterior teeth, Cuban American children had a significantly lower mean DFS than did Mexican Americans and Puerto Ricans. No significant differences were found among the children of the three Hispanic groups in the DFS of mesial and distal tooth surfaces of posterior or anterior teeth. Puerto Rican children had 58 percent of the carious activity occurring on occlusal surfaces, and the Cuban American and Mexican American children had 56 and 53 percent, respectively. If the buccal and lingual tooth surfaces are included, then the percent age of pits-and-fissures of posterior tooth surfaces affected by dental caries will increase to about 79, 85, and 85 percent of the total DFS scores in Cuban Americans, Puerto Ricans, and Mexican Americans, respectively.

Periodontal Disease

Puerto Ricans, ages five through 44 years of age, had a significantly higher prevalence of gingivitis than Cuban Americans and Mexican Americans (Table 5). In the oldest age group, Puerto Ricans and Mexican Americans had a significantly higher prevalence of periodontal pockets than Cuban Americans. Puerto Ricans, 18 to 74 years of age, also had significantly higher mean DI scores than Cuban Americans (Table 6). In a regression model controlling for the confounding effects of age, sex, diabetes (presence or absence of diagnosed diabetes), and oral hygiene status, Puerto Ricans remained with the highest prevalence of periodontal disease relative to the other two Hispanic groups. Diabetes status was included because it has been shown in a longitudinal study that diabetics had more gingivitis and periodontal pocketing than non-diabetics.[14]

Discussion

Untreated dental caries in Hispanic children and adults and the relatively high mean number of missing teeth in Cuban American and Puerto Rican adults compared with Mexican Americans and other Americans[3] are the two most important oral health problems facing Hispanics. It is important to note that Hispanic adults had twice higher mean number of decayed teeth than Hispanic children. This finding suggests that there is a strong cohort effect in the Hispanic population with different age groups experiencing different exposure to preventive and dental services. The presence of decayed teeth, however, does not mean that treatment of all carious lesions is urgently needed. Unfortunately, the criteria used during HHANES to measure caries[15] do not provide information about the severity of the carious lesions and therefore a decision on what mix of preventive and treatment services will be needed cannot be made. Also, the NIDR Restorative Treatment Need Index,[15] used during HHANES, does not provide information about the need for fissure sealants and whether small carious lesions should be restored or followed with recommendation for fluoride application to arrest the progress of the lesion. Given the concentration of carious activity in the pits and fissures of posterior teeth in Hispanic children, however, the effectiveness of fissure sealants in preventing dental caries on those surfaces will be higher than other preventive methods.

In a previous analysis of National Health Interview Survey (NHIS) data collected during 1978–80, Mexican Americans, Cuban Americans, and Puerto Ricans visited the dentist less frequently than White non-Hispanics.[16] Mexican Americans had the lowest proportion of persons who went to a dentist within a year compared with Puerto Ricans and Cuban Americans. Mexican American use of dental services resembled the pattern of dental care received by Black

TABLE 5—Percent Distribution of Dentate Mexican Americans, Cuban Americans, and Puerto Ricans by Periodontal Disease Status* and Age, HHANES, 1982–84

	Gingivitis Only			Periodontitis		
Age (years)	Mexican American (95% CI)	Cuban American (95% CI)	Puerto Rican (95% CI)	Mexican American (95% CI)	Cuban American (95% CI)	Puerto Rican (95% CI)
5–17	76.6	65.1	90.0	.2	.0	.1
	(73.4, 79.8)	(59.4, 70.8)	(87.3, 92.7)	(−.14, .54)	—	(−.2, .4)
18–44	82.4	81.2	90.0	7.0	2.1	8.2
	(79.3, 85.5)	(77.1, 85.3)	(87.1, 92.9)	(4.9, 9.1)	(.6, 3.6)	(5.5, 10.9)
45–74	59.1	72.3	65.1	35.7	20.8	32.4
	(53.2, 65.0)	(67.9, 76.7)	(58.9, 71.3)	(29.9, 41.5)	(16.8, 24.8)	(26.3, 38.5)

*Periodontal Disease Status is based on Periodontal Index Scores.[12] Those with no periodontal disease are not included and therefore the percentages do not add up to 100.

TABLE 6—Mean Number of Debris Index (DI) and Calculus Index (CI) Scores[13] (and 95 Percent Confidence Intervals) of the Means for Dentate Mexican Americans, Cuban Americans, and Puerto Ricans, Ages Five through 74 Years, HHANES, 1982–84

Age (years)	Mexican American	Cuban American	Puerto Rican
Debris Index scores			
5–17	.80	.72	.78
	(0.76, 0.84)	(0.66, 0.78)	(0.74, 0.82)
18–44	.75	.62	.86
	(0.70, 0.80)	(0.57, 0.67)	(0.81, 0.91)
45–74	.94	.72	1.04
	(0.84, 1.04)	(0.65, 0.79)	(0.95, 1.13)
Calculus Index scores			
5–17	.09	.04	.16
	(0.08, 0.10)	(0.02, 0.06)	(0.13, 0.19)
18–44	.67	.43	.77
	(0.63, 0.71)	(0.37, 0.49)	(0.70, 0.84)
45–74	1.30	.75	1.23
	(1.22, 1.38)	(0.68, 0.82)	(1.11, 1.35)

Americans. Puerto Ricans were the only group for whom dental visits were not significantly influenced by family income level. In this study, the dental caries prevalence of Mexican Americans parallels that found in Black Americans during the 1985–86 NIDR survey.[3] (Comparisons between HHANES findings and other national surveys are limited by the differences in sampling strategies. Examination criteria used during HHANES, however, were those used by NIDR, and the training of the dental examiners in HHANES was also carried out by NIDR staff.) Puerto Ricans and Cuban Americans had a dental caries distribution that was in between those of Mexican Americans and Blacks, and White Americans in the NIDR survey. The influence of dental visit patterns, income, and dental education may partly explain the differences in the mean number of missing teeth among the three Hispanic groups.

The results of the analysis of HHANES dental data reported here raise a number of methodological questions about the meaning of the DMF score. Conventionally, the DMF score has always been analyzed as a single composite index. Moreover, analysis of the DMF score of an individual assumed that all filled teeth have been treated because they were previously carious. The filled component of the DMF index represents a decision made previously by the dentist of the examinee. As has been documented by several investigators[17,18] the diagnostic criteria used by dentists to decide on need for restorative treatment are plagued with considerable variations. In a study in Scotland, where 15 general practitioners examined 18 patients and estimated their restorative treatment needs, the range of teeth needing treatment for each patient varied according to the examining dentist.[17] For the 18 patients together, the costs of the treatment planned by the 15 dentists ranged between 92.5 and 478.6 British pounds. These findings raise doubts about the validity of analytic methods for the DMF index that combine the three components of the index as a single variable.

As in Mexican Americans, the prevalence of gingival inflammation and periodontitis in Puerto Ricans and Cuban Americans is higher than national averages.[3] Puerto Ricans had the highest prevalence of gingivitis. Puerto Ricans and Mexican Americans also had a higher prevalence of calculus and debris than Cuban Americans. The level of DI and CI scores in Mexican Americans and Puerto Ricans, 18–74 years of age, is higher than that determined to be compatible with an acceptably low level of periodontal disease.[19]

In conclusion, the oral health status of Hispanic-Americans can be summarized as follows:

- Total tooth loss is not a public health problem in Hispanic Americans examined during HHANES. However, the dentate Cuban American and Puerto Rican adults have about twice as many missing teeth than White non-Hispanics.
- In children, while the prevalence of dental caries is low, using the World Health Organization criteria,[20] the tooth surfaces most affected by dental caries are the pits and fissures of posterior teeth rather than smooth tooth surfaces. These findings support the need for sealant programs to prevent dental caries.
- Hispanic adults had twice higher mean number of decayed teeth than Hispanic children. Puerto Ricans and Cuban Americans had a higher mean number of filled and missing teeth than Mexican Americans. The distribution of dental caries in Mexican Americans was similar to that found in Blacks in 1985–86.[3] Puerto Ricans and Cuban Americans had a dental caries distribution between that of Black and White Americans.[3]
- The prevalence of gingivitis in Hispanics is higher than that found in White non-Hispanics.[3] Puerto Rican children and adults had the highest prevalence of gingivitis among the Hispanic groups.

ACKNOWLEDGMENTS

This investigation was supported by a grant from the National Coalition of Hispanic Health and Human Services Organizations (COSSMHO), Washington, DC.

A summary version of this paper was presented during the 1988 meeting of the American Association of Public Health Dentistry, Washington, DC.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription Price is $80/year US; $120/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Disease Control Priorities in Developing Countries: Health Policy Responses to Epidemiological Change

Dean T. Jamison, PhD, and W. Henry Mosley, MD, MPH

ABSTRACT

Health systems in developing countries are facing major challenges in the 1990s and beyond because of a growing epidemiological diversity as a consequence of rapid economic development and declining fertility. The infectious and parasitic diseases of childhood must remain a priority at the same time the chronic diseases among adults are emerging as a serious problem. Health policymakers must engage in undertaking an epidemiological and economic analysis of the major disease problems, evaluating the cost-effectiveness of alternative intervention strategies; designing health care delivery systems; and, choosing what governments can do through persuasion, taxation, regulation, and provision of services. The World Bank has commissioned studies of over two dozen diseases in developing countries which have confirmed the priority of child survival interventions and revealed that interventions for many neglected and emerging adult health problems have comparable cost-effectiveness. Most developing countries lack information about most major diseases among adults, reflecting lack of national capacities in epidemiological and economic analyses, health technology assessment, and environmental monitoring and control. There is a critical need for national and international investment in capacity building and essential national health research to build the base for health policies. (*Am J Public Health* 1991;81:15–22)

Introduction

The policy debate in international health has often been polarized around conflicting viewpoints on such issues as preventive versus curative services, selective versus comprehensive primary health care, or integrated versus vertical programs. As we approach the 21st century, it is becoming clear that framing the issues in these terms will not enlighten the policy process, primarily because it limits the options largely to actions that can be carried out directly by ministries of health. Profound social and economic transformations are projected to impact on health in the developing countries in the 1990s and beyond; implications for the epidemiological profiles of these countries will be dramatic.[2–4] A more comprehensive analytical approach is required to formulate health policies that will not only respond to but actually guide the development process to maximize its health gains, minimize its potential adverse consequences, and deal cost-effectively with the emerging quantitative importance of noncommunicable diseases.

Over the next decade there will indeed remain perhaps 30 to 40 countries in the lowest income bracket where the health problems will be dominated by the infectious and parasitic diseases of childhood along with undernutrition and high fertility.[5] Most of these are in Sub-Saharan Africa and South Asia, and intervention strategies must continue to focus on establishing basic infrastructures and delivering established, low-cost technologies.[6] At the same time, however, there will be a larger group of countries, predominantly in Latin America and East Asia, that are newly emerging into the middle income category. Most of these countries are not free of the infectious diseases, yet at the same time are beginning to face a new set of health problems related to rapid urbanization and industrialization.[3,7,8] These include: injuries, occupational diseases and, increasingly, preventable chronic diseases among an aging population.[9] Such a growing epidemiological diversity among and within countries in the developing world demands a flexible approach to international health policy formulation.

Policy Development

It is useful to consider health policy development as involving three complementary tasks: first, *identifying the major disease problems,* assessing their social and economic consequences, and evaluating the costs and effectiveness of alternative intervention strategies; second, *designing health care delivery systems* including establishing the human and physical infrastructures, providing for drugs and logistical support, and developing managerial capacities and funding mechanisms; and third, *defining and choosing what governments can do* through the full range of policy instruments that are at their disposal in the areas

---

This paper, invited by the editor, draws in part on a forthcoming book edited by Jamison and Mosley[1]; it is based on work undertaken and supported by the Population, Health, and Nutrition Division of the World Bank. The views expressed in this paper are those of the authors and do not necessarily represent those of the World Bank. The authors are indebted to Drs. D. A. Henderson and A. R. Measham for valuable comments.

of persuasion, taxation, regulation and the provision of services.

Like a three-legged stool, coherent health policies require a solid foundation of technical analysis in all three areas in order to identify effective strategies and establish sustainable programs. Through the 1960s and 1970s the second task, designing institution-based delivery systems, (generally following a Western medical model) was the dominant theme in health policy formulation for the developing world. It was in this period that the policy debates centered around the relative allocation of resources for preventive versus curative services and, when disease eradication programs were being implemented, vertical versus integrated programs. The Alma Ata Conference on Primary Health Care in 1978 introduced the principle of "Health For All."[10] Conceptually this encompassed all health problems in the population, was community-based, and involved all sectors of government. Given the resource constraints in the health sector, many health professionals and donors narrowed the agenda, limiting consideration to childhood communicable diseases.[11] This led to selective primary health care programs focusing largely on population-based technical interventions such as oral rehydration therapy and immunizations for child survival[12] which, in turn, led to policy debates about the relative merits of selective versus comprehensive primary health care interventions.[13]

The third task, assessing the full array of government instruments available, particularly those outside the traditional purview of ministries of health (such as regulation and taxation) to protect and promote the health of populations is not well established in much of the developing world. The full range of instruments is, however, fully entering the public debate on policy in a number of industrialized countries. For example, in the United States the process was initiated with the publication of "Healthy People: The Surgeon General's Report on Health Promotion and Disease Prevention" in 1979 which defined a set of health goals for 1990 for infants, children, adolescents, adults, and the aged.[14] To achieve these goals, 15 priority areas for intervention were identified and grouped under three strategic approaches: preventive health services, health protection, and health promotion.[15] Preventive health services included: primary preventive interventions such as immunizations and family planning, secondary prevention for conditions like high blood pressure as well as curative services for such conditions as sexually transmitted diseases. Health protection encompassed areas where regulation and taxation would be important including toxic agent control, occupational safety, accident prevention, and fluoridation. The health promotion strategies—involving behavioral changes related to smoking, alcohol and drug abuse, diet and exercise—required government interventions not only in education but also through regulation and taxation.

The process of setting national objectives in the US has now been extended with *Healthy People 2000: National Health Promotion and Disease Prevention Objectives.*[16] Based on three years consultation with more than 300 national organizations and state health departments, the goals have been reformulated to go beyond mortality reduction: to increase the span of healthy, disability-free life; to reduce disparities in health by giving more attention to the vulnerable high risk groups such as the poor, minorities, and the elderly; and, to increase access to basic health services.[16] In this context, new priority areas have been added such as cancer screening, AIDS, preventive health services, and surveillance.

Three factors have been key to the successful mobilization of public and professional interest and debate in the United States.[17] First, there was a clear definition of the health problems of concern and their social and economic as well as medical determinants. Second, the 15 priority areas selected for health improvement were further subdivided into 227 health promotion objectives for the 1980s.[18] These detailed objectives represented precise, quantifiable management strategies which were realistic in terms of resource constraints and time frame for implementation, yet demanding enough to push the system to new levels of capability. Third, the *process* of problem identification and health policy formulation involved the broadest participation of all segments of society.[19] On the one hand, a considerable breadth of expertise was drawn from the fields of epidemiology, management sciences, economics, behavioral sciences, and communications to define the problems and issues to be addressed and propose strategic alternatives. On the other hand, there was broad political and public participation in devising solutions. The necessity of this third step (which is rare in developing countries) cannot be overemphasized: the policy formulation process should be an educational experience about the health problems for all concerned since it will be necessary to reach a wide national consensus on issues, policies and implementation strategies which will cut across many sectors including finance, trade, agriculture, transportation, industry, education, and others. It must also be emphasized that successful mobilization of debate and concern is far from sufficient, as the example of the US also, unfortunately, attests. Where the political will for public action is lacking and resources are unallocated, health outcome indicators, such as infant mortality rates among minority groups, can remain shamefully high.

A first task in a comprehensive analysis of the health sector requires an estimation of the burden of disease in the population. This should be done in a framework that considers not only the capacity of the health system to deal with these diseases but also the rapidly changing social, economic, and political context that may be influencing both the structure and organization of the health system as well as disease risks and health behaviors in the population. Because of the extraordinary diversity among developing countries, it is unrealistic and, indeed, inappropriate to come up with global policies; rather, what is presented here is a conceptual and analytical approach with illustrations of the range of factors which must be considered in any particular setting. This approach takes into account that there will be a continuing evolution of disease control priorities based on the social and economic transformations countries are undergoing with their accompanying demographic and epidemiologic transitions.[20]

The Changing Determinants of Disease

A first determinant of the changing health picture developing countries will be experiencing is the demographic transition, largely driven by the rate of fertility decline. This will produce major changes in the age structure of populations which will have a large impact on the health picture.[21] Table 1 taken from World Bank projections for the period 1985 to 2015 illustrates the changing demographic and health picture for developing countries worldwide.[22] Overall, slower growth of the childhood population coupled with declining death rates are projected to reduce the health problems of all age groups. But this is more than counterbalanced by the

TABLE 1—Health Problems of Different Age Groups

Age Group	Population in Developing Countries, millions 1985	Population in Developing Countries, millions 2015	Deaths in Developing Countries, millions 1985	Deaths in Developing Countries, millions 2015	Important Health Problems: Problems on the Unfinished Agenda	Important Health Problems: Neglected and Emerging Problems
Young children (0–4 years)	490	626	14.6	7.5	Diarrheal disease ARI Measles, tetanus, polio Micronutrient deficiencies Malaria	Injury
School-age Children (5–14 years)	885	1196	1.6	1.3	Schistosomiasis Geohelminth infection	Adolescent pregnancy Disability
Young adults (15–44 years)	1667	2918	5.0	6.0	Maternal mortality Malaria Excess fertility	Tuberculosis Injury AIDS STDs Mental Illness
Middle-aged (45–64 years)	474	1131	5.9	10.4		Cardiovascular disease Cancers COPD
Elderly (65+ years)	153	358	11.0	22.5		Disability Depression
TOTALS	3669	6229	37.9	47.7		

SOURCE: Jamison and Mosley, (forthcoming)[1]

NOTE: Many of the conditions for older age groups manifest themselves clinically long after the processes leading to the clinical condition have been initiated; preventive intervention will therefore need to be directed to younger ages.

AIDS: acquired immunodeficiency syndrome
STDs: sexually transmitted diseases
COPD: chronic obstructive pulmonary disease
ARI: acute respiratory infection

rapid increase in the adult and aging population. Regionally the picture is much more diverse. The population of children under age five in Latin America and Asia will increase by only 2 percent to 5 percent, respectively, in size. By contrast, this age group is projected to grow 38 percent in the Middle East and 70 percent in Sub-Saharan Africa from 1985 to 2015. Clearly the future requirements for maternal and child health services will be quite different across these regions. At the other end of the age spectrum a very different picture emerges. In all of these regions the populations over age 65 will be dramatically growing in size with projected increases ranging from 134 percent to 164 percent. This continuing growth in the older age groups is due to a phenomenon called the "momentum" of population growth; it is a consequence of the large numbers of children born in the past when fertility was high who advance through older age groups over time. The result is that essentially all developing countries will have to provide for the health needs of a rapidly increasing adult and aged population for many years into the future.[4] A broad assessment of how to meet these needs may be found in Feachem, *et al*, (forthcoming).[23] At the same time, in those countries where the fertility transition is barely underway (largely in Sub-Saharan Africa), policymakers must simultaneously plan to continue to rapidly expand maternal and child health services.

A second determinant of the changing health picture is the major social and economic trends which are transforming the risk factors themselves.[24] The most obvious indicator of these trends is the shift from rural to urban living. In 1985, barely over 30 percent of the population of the less developed regions lived in urban areas, but this pattern is changing rapidly.[25] The urban population will reach 40 percent by the year 2000 and surpass 50 percent by the year 2015. Already seven of the world's 12 megacities (population 10-million or more) are in developing countries. By the year 2000 the developing world will add six more cities to this number.

A shift from a rural subsistence economy to an urban market-oriented industrial economy is generally associated with reductions in risks to communicable diseases because of better sanitation in urban areas. At the same time, however, economic growth brings with it new health problems.[26] Very high rates of injuries related to motor vehicles, industrial accidents, and toxic chemicals (e.g., pesticides) are usually seen in developing countries because of a lack of resources and institutions to establish and enforce safety measures.[27] Undernutrition may diminish because of improved markets, only to be replaced by overnutrition with rising risks of death due to obesity, hypertension, atherosclerosis, and diabetes.[28] Rising incomes also bring changes in lifestyle including increases in smoking, alcohol use, and substance abuse, all of which are expected to increase the risk for chronic diseases.

An analysis of the tobacco-related diseases provides an excellent illustration of how a disease-oriented approach can inform health policy.[29] In the United States it is now well established that tobacco use is responsible for more than 30 percent of all cancer deaths as well as being among the strongest risk factors for chronic obstructive pulmonary disease and ischemic heart disease.[30,31] In recent years, rising rates of lung cancer associated with cigarette consumption have been observed in Japan, Singapore, and Shanghai.[32] A recent analysis by the World Bank has documented a direct relationship between tobacco consumption and higher levels of national income among developing countries.[33] This relationship is not coincidental. Rather, it is driven by promotion, pricing, tax policies, and even international trade relations. The impact of the latter is best attested by the rapid increases in cigarette consumption among young people in several east Asian countries where multinational tobacco corporations have recently opened new markets, assisted in some cases by aggressive (even coercive) trade policies of the United States Government.[34]

Taking China as an example, Peto projects that if current smoking trends continue due to a failure to introduce the array of policies necessary to reduce tobacco consumption in the next several years, an estimated two million Chinese men will die annually from tobacco-related health problems by the year 2025.[35] Cumulatively, one may anticipate 50 million tobacco-related deaths among the 500 million Chinese now under the age of 20. National policies to protect populations from tobacco-related diseases clearly must move beyond the usual realm of the health sector into areas of regulation and taxation of the industrial enterprise related to the manufacture and distribution of tobacco products and, in many countries including the United States, ultimately into a restructuring of rural economies where tobacco is produced.[36-38]

The AIDS (acquired immunodeficiency syndrome) epidemic provides another illustration of some of the links between economic development and disease transmission. In assessing the situation in Sub-Saharan Africa, Over and Piot document a strong correlation between the rate of HIV infection in 18 cities, a high ratio of males to females in urban centers and a low level of female education.[39] The implications of these findings are that AIDS transmission is facilitated by development strategies which favor males for urban employment. This generates a high demand for prostitutes; prostitution, in turn, is facilitated by low levels of female education so that women have few alternative economic opportunities open to them. An AIDS-control program must go beyond promoting the use of condoms and treating sexually transmitted diseases (STDs) and consider broader social policies relating to female education and labor force participation.

Epidemiologic Polarization

The epidemiologic transition in the developing world is neither a steady nor a uniform process. The great variations in life expectancy between countries attests to this; as of 1988, a dozen Sub-Saharan African countries still had life expectancies under 50 years, while an equal number of countries in Latin America and Asia (including China) had life expectancies of 70 years or greater.[40] Additionally, within developing countries (and developed countries as well) wide disparities in health conditions across different social classes or different regions are not uncommon. Frenk and colleagues have referred to these disparities as "epidemiologic polarization" and "epidemiological stagnation."[3,41] These disparities are not limited to the infectious diseases of infants and children but include the chronic diseases of adults as well.[7,23] A centrally important conclusion for health policy is that in most developing countries pre- and post-epidemiological transition problems will coexist.[41] As Foege and Henderson have observed, the developing countries ". . .will not have the luxury of dealing with two kinds of problems sequentially. For the remainder of this century they will be dealing with both simultaneously."[42]

The increasing burden of chronic disease is initially likely to affect the relatively more affluent and politically vocal older groups who are growing in numbers. This being the case, governments will need to take great care to assure that the infectious diseases which predominantly affect children and the poor are not neglected in the face of resource demands placed in large measure by the more affluent. The challenge is to develop equitable policies and strategies to meet these unprecedented conditions in the developing world.

Assessing Disease Control Priorities

The World Bank, as a part of an exercise to assess the cost and effectiveness of alternative intervention strategies for over two dozen acute and chronic diseases of adults and children, commissioned a series of analytical studies, each co-authored by individuals combining economic, epidemiological, and clinical expertise. Cost effectiveness was expressed in terms of dollar cost per discounted healthy life years gained (DHLY). The details of these studies are reported elsewhere.[43] Several general conclusions which emerged from this undertaking will be described here in terms of their implications for the process of policy development in developing countries.

First, while child survival interventions (immunizations, provision of antenatal and delivery care, vitamin A supplementation, improvements in domestic hygiene, oral rehydration therapy [ORT] for diarrheal diseases in high mortality environments, and antibiotic therapy for acute respiratory infections) appear to be highly cost-effective ($5-50 per DHLY), there were a range of adult health interventions which were estimated to be equally cost-effective. Among the most prominent are: anti-smoking campaigns plus tobacco taxes, passive case finding and short-course chemotherapy for tuberculosis, the targeted management of sexually transmitted diseases, cataract surgery, the use of condoms to prevent HIV transmission, and hepatitis B immunization to prevent liver cancer and cirrhosis. At the other extreme, the cost per DHLY for a number of adult diseases is so high (greater than $1000) that public policy should probably discourage their use in settings where health resources are severely constrained. Among these are coronary bypass surgery, mitral valve replacement for rheumatic heart disease, medical management for hypertension, and tertiary management of lung, liver, esophageal, and stomach cancer. With reference to cancer, it should be noted that cancer pain control appears to be a relatively cost-effective intervention for adults ($150 per DHLY) reaching the same level as: maternity care services for maternal mortality; public preventive campaigns to prevent cardiovascular disease; medical management of angina; and insulin management of insulin-dependent diabetes melitis.

This analytical approach revealed a number of neglected and emerging health problems which should be accorded far higher priority. Topping the list of emerging problems are the tobacco-related diseases which, interestingly enough, were not even mentioned in the 1980 World Bank Health Sector Report.[44] Tuberculosis appears to be the greatest "neglected" disease.[45] In 1990 there will be an estimated 8.4 million new cases and 2.7 million deaths, over two-thirds of which will be among productive adults (ages 15–59), primarily the poor. Significantly, this disease alone accounts for about 37 percent of an estimated seven million avoidable adult deaths in the developing world.

Some findings challenge the current international donor commitment to global priority setting. Provision of ORT *in low mortality environments* (at $200 per DHLY) is estimated to be about 20 times less cost effective than tuberculosis control (using passive case detection and short course chemotheraphy) or leprosy rehabilitation. Even cervical cancer screening (Papanicolaou smears) are estimated to be an equally good buy for the money. In *high mortality environments,* in contrast, ORT can be quite cost-effective, underscoring the need for analysis at the country or even district level.

A major observation from the World Bank exercise is the paucity of empirical data from a majority of the developing countries about most of the major chronic diseases of adults.[23,46] Considering that, on a global level, more than half the world's deaths due to cancers and cardiovascular diseases, three-fourths of the injury deaths, and 85 percent of the chronic obstructive pulmonary disease deaths occur in developing countries, the virtual absence of any information about the levels, trends, and determinants of these conditions for the majority of the world's population is truly tragic. Given this lack of developing country data, most of the estimates of the cost-effectiveness of interventions for the World Bank study had to be derived from research carried out in the industrialized world. While these estimates are probably reasonable in grossly illustrating the relative cost-effectiveness of alternative interventions, the actual cost-effectiveness of a particular intervention could easily vary by two- to tenfold or more in any given situation, depending on a host of local factors. For example, with interventions, like immunizations, that require total population coverage, cost-effectiveness is strongly conditioned by the underlying level of disease incidence and case fatality rates. For therapeutic interventions, cost-effectiveness is determined not only by the institutional costs of reaching the target group and then making the correct diagnosis, but also by the probability that appropriate therapy will be prescribed by the caregiver and that the patient will actually comply with the treatment regimen.[47–50] Similarly, the costs of monitoring and enforcing regulatory approaches depend upon the reach and capability of the governmental infrastructure.

Implications for National Governments

It should be clear that there is an urgent need to reassess health sector priorities in developing countries. National health policy assessment can be usefully informed with a consideration of global trends and findings such as presented above, but it must quickly evolve to a critical analysis of the local epidemiological picture cast in its social-cultural, administrative, economic, and political context. Such an approach to policy formulation must begin by assessing the full range of health problems in a society; examining broadly their demographic, social, and economic determinants; and identifying alternative courses of action in all of these areas which could improve the situation. This last step must take into consideration the costs and effectiveness of all possible instruments of government intervention including taxation and regulation as well as persuasion and the direct provision of services.[4]

Many governments will need to create new institutions and reconfigure old ones to build the capacities required for policy analysis and implementation. Among the analytical and technical capacities required are the following:

- *Demographic analysis*—These capabilities provide the fundamental underpinnings for a population-based health system. Demographic data provide the basis for designing intervention strategies as well as for assessing the impact of the disease burden on the population.
- *Epidemiological surveillance*—While some epidemiological surveillance is carried out in most developing countries, it is usually limited to selected infectious diseases. These capacities will need to be greatly strengthened as health program strategies move more toward interventions involving regulation, taxation, subsidies, and information programs in order to reduce acute and chronic disease risks by changing behaviors and improving environmental conditions.
- *Economic and financial analysis*—These capabilities will be essential to measure the cost-effectiveness of alternative intervention strategies as well as to assess the overall claim of the health sector on scarce development resources.
- *Health technology assessment and control*—Institutional capabilities in this area must include not only the assessment of the effectiveness of new drugs, vaccines or treatments, but also their costs and benefits when introduced into the health system.
- *Environmental monitoring and control*—In most developing countries capabilities in this area must be greatly expanded beyond the traditional water and sanitation activities to monitor and control (through taxation as well as regulation) a much broader range of environmental risks including air pollution, toxic wastes, traffic hazards, and other injury risks.
- *Occupational safety*—Rapid urbanization and industrialization in developing countries is often associated with risks of work-related injury five to 10 times higher than in developed countries. There is a major need to develop the capacity to monitor and control occupational health risks.

While many of these institutional capacities exist in some measure in health ministries, their functions are limited for a variety of reasons including lack of professionally qualified personnel, limited resources and, particularly, lack of enforceable statutory authority. If health systems are to be transformed to meet the challenges of the future, a high priority must be given to empowering health ministries to carry out the monitoring and regulatory tasks needed to effectively function in new areas. In addition, mechanisms need to be established that will give them an appropriate voice in tax policy. Ultimately these capacities will need to be developed at regional and local levels within countries as well as at the national level.

Implications for International Aid

Official development financing for health by bilateral and multilateral donors in 1986 amounted to $3.7 billion with the US contribution accounting for 16 percent of the total.[51] While external support represents only a small fraction of the total public and private sector health expenditures in developing countries, in fact, because much of the donor assistance is directed toward the poorest countries, its proportional impact in influencing health policies and program strategies is relatively large. This is particularly true when it promotes policies which lead to a reallocation of national resources. The impact of the donor-driven child survival initiative in promoting immunizations and oral rehydration therapy worldwide is an excellent illustration of this.[52]

TABLE 2—Instruments of Aid

Objectives	Modality of Assistance: Program Implementation	Modality of Assistance: Capacity Strengthening
1. Service Delivery	Supports acquisition of drugs, equipment, and technical assistance, for delivery of EPI, vector control programs, hospital services, etc.	Invests in institutional development and staff training to improve efficacy of service delivery—e.g. through improved logistics and supply systems.
2. Policy Improvement	Identifies specific areas of policy improvement (e.g. tobacco advertising bans or introduction of cost-recovery mechanisms) and includes them (usually with conditionality) as part of an assistance package.	Invests in development of policy and planning departments in ministries or universities; invests in staff training and advanced education.
3. Undertaking Research (including epidemiologic, evaluational and economic analyses)	Conducts (perhaps with involvement of aid agency or expatriate staff) research or analyses to strengthen formulation of policy or delivery of service.	Invests in national (and international) capacity for undertaking research relevant to epidemiological and economic conditions of developing countries. This capacity strengthening involves both institutional and human resource development.

In looking to the future, it is useful to categorize international aid on the basis of whether its objective is to: 1) support the provision of services; 2) influence the policy environment; or 3) support research. Table 2 divides approaches to meeting these three objectives into two modalities of assistance: program implementation and capacity strengthening. Program implementation is largely oriented toward short-term results, while capacity strengthening generally requires long-term investments in institutional development. Traditionally, the dominant role of international assistance has been to provide services and related commodities where they were unavailable or inadequate; most donor support to child survival programs falls in this category. Recently, more attention is being given to structuring aid to change the policy environment, either directly, for example, by channeling more support to private and non-profit NGO (nongovernmental organizations) sectors, or indirectly by attaching conditions to aid packages, for example, by requiring cost recovery or extension of services to underserved populations. Presently only a small fraction of aid is directed toward research, much of which, in fact, is in specialized programs such as the Tropical Disease Research Program or in a few institutions like the International Center for Diarrheal Disease Research, Bangladesh.[53]

The earlier discussion has highlighted the fact that developing countries are now moving through the epidemiologic transition at very different paces and often incompletely. As a result there is a great diversity both in health conditions and in institutional capacities among and within countries.[2] This creates a far more diffuse planning environment than existed when most of these countries were still in a pre-transitional stage two or three decades earlier. No longer can a few strategic objectives command central importance for health policy. Rather, a much broader range of relatively less prominent health conditions and associated interventions will compete for resources and attention. In light of this, and given the fact that extremely little is known about the levels, trends, and determinants of the majority of diseases afflicting populations in the developing world, the conclusion is inescapable that as far as donor assistance is concerned, far higher priority should be given to research, both building research capacity and conducting research to strengthen the formulation of health policy. This, in fact, is the conclusion reached by the Commission on Health Research for Development in its recent report.[53] The Commission specifically placed a high priority on local epidemiological and operational analyses which they labeled as "Essential National Health Research" (ENHR).

Broadening the array of diseases for consideration to encompass all ages and expanding the arena of policy options to include the full range of instruments for government intervention will demand a diversity of analytical skills. National governments will require broad technical competence not only in the biomedical and clinical sciences including epidemiology but also in economics, sociology, anthropology, the management sciences, and communication. In most countries, new institutions may need to be developed. The international donor community generally, and the United States in particular, could most effectively use its limited resources in the areas of education, training, research, and technical assistance, where it has strong comparative advantage.[54] Furthermore, because most of the major disease problems are actually of global concern (e.g. tobacco-related diseases, substance abuse, AIDS, injuries, occupational diseases, cardiovascular disease, cancer, malnutrition) much could be gained through international collaborative endeavors in these disease control efforts.

Conclusion

For over a decade the international public health community has given a priority to the communicable childhood diseases. This had been appropriate. The problems are major, the technological and epidemiological tools have become powerful, and the payoff for adapting and applying what is known is high. While the implementation strategy for selective primary health care as originally proposed by Walsh and Warren may have been oversimplified and too narrowly concerned with infectious diseases, the problem-oriented, population-based conceptual approach is fundamentally correct.[11,55] Furthermore, as more and more governments have seriously addressed the problem of child survival, the range of interventions has broadened.[56] For example, diarrhea control programs have moved from simply relying on packets of oral rehydration salts to the use of homemade fluids, the dietary management of diarrhea, the promotion of personal hygiene, and use of soap. More importantly, policy recommendations supporting child survival have now expanded widely, encompassing such issues as female education and the status of women.

The rapid demographic transition that many developing countries are undergoing is now producing great epidemiological diversity among developing countries; this demands that health policymakers consider a broader range of options. Over the next 25 years it is not unreasonable to project a 50 percent to 60 percent decline in the numbers of deaths among infants and children related to advances in child health coupled with rapidly declining birth rates which will stabilize the numbers of newborns from year to year over much of the world. Overall, however, there will be a rise in the total number of deaths as the population evolves toward an older age structure. The epidemiological transition is not occurring uniformly, however, and most countries will have a large lingering burden of communicable diseases among children, particularly in Sub-Saharan Africa where the fertility transition has hardly begun. This situation will impose the greatest challenge on health systems operating under constrained resources to select the most effective and efficient means of disease prevention, case management, and rehabilitation.

It must be emphasized that extending the range of choices means not only choosing to implement new initiatives but also choosing to reduce investments of public funds in health care activities that are clearly not cost-effective. While this may be difficult, given the traditions of Western medical practice, the fundamental issues of equity as well as efficiency are involved. Efficient resource allocation is desirable in every sector. In the health sector, however, in a very direct way, unnecessary death, disability, and illness occurs if resources are committed to one intervention when another has higher health gains per unit of expenditure. The human cost of uneconomic resource allocation is very real and very large. Perhaps even more than in other sectors, then, the imperative exists for policymakers in the health sector to undertake constant assessment of intervention cost-effectiveness.

Probably the most important advance in policy formulation that could come from a disease-control strategic approach is a willingness to consider a range of options available to governments beyond the direct provision of health services. Particularly important as countries are moving through an accelerated process of economic development is the judicious use of regulation, legislation, taxation and subsidies to promote or discourage enterprises, activities, or behaviors which may have health consequences. Also, the importance of mass communication for social mobilization to promote health cannot be over-emphasized. A high priority problem demanding such multi-faceted policy intervention and global cooperation is tobacco consumption.

It is universally recognized that improved health in the broadest sense is a fundamental indicator of the development process. As the Nobel Laureate T. W. Schultz observed, ". . .the wealth of nations (has) come to be predominantly the acquired abilities of people—their education, experience, skills, and health."[57] The task of health policy is to define clear, realistic, and measurable objectives which can guide the development process toward effectively and efficiently producing good health for all. ☐

Patterns of Medical Employment: A Survey of Imbalances in Urban Mexico

Julio Frenk, MD, MPH, PhD, Javier Alagon, DPhil, Gustavo Nigenda, MA, Alejandro Muñoz-delRio, BSc, Cecilia Robledo, BA, Luis A. Vaq́uez-Segovia, BA, and Catalin Ramírez-Cuadra, BA

ABSTRACT

This article quantifies the magnitude and correlates of the major imbalances affecting the employment of physicians in the urban areas of Mexico. Since the early 1970s the country has experienced a rapid increase in the supply of doctors, which its health system was unable to absorb fully. In 1986, we conducted a survey in the 16 most important cities based on a probability sample of households where someone with an MD degree lived. A total of 604 physicians were interviewed for a response rate of 97 percent.

The unemployment rate was 7 percent of potentially active physicians; 11 percent held a nonmedical job, and another 11 percent exhibited low productivity and/or income. All in all, we project that 23,500 physicians in these cities were either unemployed or underemployed.

This medical employment pattern was analyzed against five independent variables: generation (i.e. the year in which the physician started medical school), gender, social origin, medical school quality, and specialty. Apart from generation, type of specialty exhibited the strongest correlation with the employment situation of a physician.

The results suggest that higher education and health care in Mexico may be producing rather than correcting social inequalities. Policy alternatives are discussed to restore a balance between the training of physicians, their gainful employment, and the health needs of the population. (*Am J Public Health* 1991; 81:23–29)

Introduction

Among the many paradoxes of contemporary health systems probably none is so indicative of failure as the coexistence of underemployed physicians with underserved populations. This is the situation that today prevails in many countries of the world.[1] For reasons that are not yet fully understood, a wide variety of nations, with very different levels of economic development and political structures,[2] experienced during the last decades substantial increases in the supply of physicians, which the health system was often unable to absorb.[3] The result has been the appearance of manpower imbalances that have assumed manifold manifestations.[4]

In order to contribute to our understanding of the dynamics of medical employment, the present article analyzes the case of physicians in the urban areas of Mexico. Apart from the intrinsic interest of the subject, the Mexican health care system offers the analytical advantage of encompassing virtually all organizational forms of medical work, from independent practice to salaried jobs in the public sector; extreme forms of imbalances such as underemployment and unemployment exist The conceptual framework and specific methodology we have developed may be relevant to other nations.

Overview: The Medical Labor Market in Mexico

From the establishment of the first course of medicine in 1578 until the beginning of the 1970s, Mexico suffered from a chronic shortage of physicians. Starting in 1967, however, the medical education system experienced an explosive expansion. Student enrollment peaked in 1980 at 93,365, compared to 28,731 in 1970;[5] the number of medical schools reached 56 in 1979, up from 27 in 1970.[6] The underlying causes for this growth process are very complex and have been analyzed in detail elsewhere*. Briefly, two factors appear to be crucial: the increased demand for higher education from the middle classes, and the effects of the economic crisis that has intermittently affected Mexico since the mid-1970s and has channeled a large number of young people who cannot find employment in the general labor market into the universities.

The economic crisis also produced a reduced rate of growth of medical services, which made it impossible for the health care system to absorb the increased number of graduates. As a consequence, new phenomena of un- and underemploy-

For 1970: Ref. 8
For 1985: Ref. 9

ment began to characterize the medical labor market. Table 1 indicates that the supply of doctors in Mexico grew 2.7 times between 1960 and 1985.[7-9] It has been estimated that until 1971 every physician could find a salaried position upon graduation; by 1984 four graduates had to compete for every job in a health care organization.[10]

In addition, the number of positions for postgraduate residencies has remained practically constant throughout this period, at about 2,000 new positions per year. This means that the point of selection has been transferred from the medical school to the specialty residency, where entry is regulated by a uniform national examination, so that the competition for such positions has become fierce.

Since 1979 there has been a sustained effort to curb the growth of the medical education system, mostly through the institution of a joint decision-making body that brings together representatives from both the universities and the health sector.[11] As a result, only three new medical schools have been created in the past 10 years, and the annual number of graduates, which peaked at 14,099 in 1983, has declined steadily.[7] Nevertheless, the momentum of the physician population that was produced by the high growth rates of the 1970s explains why unemployment and underemployment have remained high.

Despite their visibility in the media, the magnitude of these imbalances has not been quantified with precision up to now. Estimates vary widely according to the interests represented by each source. In order to provide a scientifically validated picture of the employment situation of doctors, we conducted a national survey in 1986. Apart from its descriptive purpose, the survey also had the objective of exploring variables that may account for the performance of physicians in the labor market.

Methods

Data Source

Because the purpose of the study was to analyze the full range of employment possibilities, including the lack of a stable job, it was obvious that we could not draw a sample of traditional sites of medical work, such as offices and hospitals. Instead, we needed a representative sample of households where those holding a medical degree lived.

Such a sample was obtained from the 41,000 households that are visited every three months by the National Survey of Urban Employment, which is the official source of most labor statistics in Mexico and is carried out by the National Institute of Statistics, Geography, and Informatics. This survey covers the 12 metropolitan areas in the country and the four most important cities on the United States-Mexico border. It is a rotating panel survey, based on a stratified, multistage sample of households, where 88,050 people, representing 14,529,826 inhabitants ages 20 years or more, are interviewed. The validity and reliability of this survey have been extensively documented throughout the 17 years during which it has been in existence. Further details can be consulted in official publications on the survey.** Although this is a complex probability sample,[12] physicians constitute a relatively rare element in it; under these circumstances we assumed that they behave as a simple random sample, so that no weighting of the data is necessary in the analysis.[13]

In the last trimester of 1985, 620 physicians were identified during the regular round of the National Survey of Urban Employment. Shortly thereafter, these doctors were reinterviewed in face-to-face sessions by professional interviewers, who used a questionnaire specifically designed for our study at the National Institute of Public Health. The entire process of interviewing and coding was supervised by researchers from this institute.

Complete questionnaires were obtained from 604 physicians, for an overall response rate of 97 percent, which ranged from 94 percent in one city to 100 percent in eight cities. In Mexico future physicians are required, after four years of medical school, to complete a one-year internship in a hospital and one additional year of "social service" in a rural area before receiving their medical degrees. The sample included these interns and social service practitioners in addition to physicians who had already obtained their degrees. However, the present analysis is based on the 491 physicians who were active in the labor market. The "inactive" doctors excluded from the analysis comprise retired persons, as well as interns and social service practitioners, who do not demand employment since they are assured those positions in order to comply with the requirements for a medical degree.

Variables

Social Origin—This reflects not only the general standard of living that the physician enjoyed while he/she was growing up, but also the access to networks of relationships that may create future job opportunities. Social origin was measured through an index based on the occupation of the person who supported the physician during his/her years as a medical student (typically the father). The resulting categories were: low (e.g. manual workers, small-scale merchants), middle (e.g. technicians, teachers, clerical workers, foremen, sales agents, mid-sized merchants), and high (e.g. owners of industry, senior managers, senior government officials, professionals). In order to validate this index, we used the 1980 Census data to rank occupations along an income scale that was divided into three equal parts. The data on fathers' occupations from our survey were then matched to the Census occupation information. There was 100 percent match between our three categories of social origin and the three segments of the income scale.

Gender—Apart from its effects on productivity and job stability, gender is thought to be associated with differential access to occupational positions even af-

ter educational opportunities have become more equal among women and men.

Medical School Quality—It cannot be assumed that attending a medical school represents the same educational experience for everyone. The only objective indicator of quality available for all medical schools in Mexico is a standard examination applied to graduates at the end of their studies in order to select those who will be admitted into a residency. However, this standard test has only been in existence since the mid-1970s, so that no comparable quantitative data are available for physicians who studied earlier. For this reason, we measured quality through an opinion poll from 30 experts in medical education selected to represent four groups: authorities from medical schools, decision makers from the main health institutions in charge of medical manpower, faculty members from medical schools, and academics who have studied various aspects of medical education. Experts were given a standardized schedule to rate the quality of schools, taking into consideration elements of structure (e.g. number and qualifications of the faculty, adequacy of the facilities), process (e.g. type of curriculum, educational methodology), and outcomes (e.g. competence of graduates, success in finding jobs). They were asked to provide separate evaluations for two time periods: before and after 1970, since it cannot be assumed that the quality of the schools existing before 1970 has remained constant. Evaluations for each school in each time period were made on a scale from 1 to 4, and the scores were weighted according to the amount of information that the experts declared themselves to have about each assessment. The quality index was the average of these weighted scores. Its distribution revealed two marked cleavages, which were used as cutoff points to stratify schools into three categories of quality: inadequate, average, and good. The validity of the quality index for schools after 1971 was checked by correlating it with the average scores of graduates from each school on the standard examination for admission into residencies. The Pearson r correlation was 0.76, which was considered satisfactory.

Type of Specialty—This variable reflects the differential access to opportunities for postgraduate education. It also indicates the intensity of specialization, as measured through the following categories: no specialty, family medicine, basic specialties (i.e. internal medicine, pediatrics, gynecology-obstetrics, and general surgery), and subspecialties. Even though in Mexico the length of postgraduate training is similar for family medicine and for the basic specialties, the former is considered to represent a lower degree of specialization, since family practitioners are trained to deal with all age and sex groups. In addition, the practice settings are also different. Family medicine emerged during the 1970s as a residency program aimed at satisfying the requirements for first-contact care at the social security and other public-sector organizations. Thus, family doctors practice almost exclusively in ambulatory settings, while basic specialists also work in general hospitals.

Generation—To consider the influence of contextual variables, such as the situation of the medical labor market, we measured a variable called generation, which refers to the year in which the physician entered medical school, whether before or after 1971, the year when the policy of massive access to higher education was fully implemented. In addition to reflecting the environment to which the physician was exposed during his/her formative years, generation is very highly correlated (Pearson's r = 0.97) with age. In turn, age is related to experience, productivity, and exposure to employment opportunities, all of which affect the success of a physician in obtaining a desirable job.

Even though the data come from a cross-sectional survey, the fact that there is an unambiguous chronological order among the variables allows us to adopt a "biographical" view of medical employment. In this time order, three of our independent variables can be considered antecedent to the others, i.e. social origin, gender, and generation/age. In turn, attending a medical school occurs before postgraduate training to become a specialist. The final link in this chain, which represents the dependent variable, is medical employment.

Dependent Variable—We conceptualize the dependent variable as "medical employment pattern," built through cluster analysis of physicians sharing similar job characteristics. The detailed statistical procedure has been described elsewhere.[14] The final variable summarizes the most relevant dimensions of employment: number of jobs; position (salaried or independent); occupational level (whether the job requires less skill than what the person was trained for, e.g. whether the physician performs a nonmedical job); productivity (measured by the number of patients seen and hours worked per week); income; and job stability.

Obviously, the number of potential combinations is very large. Cluster analysis enabled us to ascertain the specific combinations that occur empirically. These combinations were grouped to form the dominant patterns, which turned out to be six:

1. Unemployment: This category was strictly defined to include those doctors who did nothing but search for a job or who had stopped looking for one because they had become discouraged.

2. Qualitative Underemployment: This pattern refers to physicians who worked outside medicine. Even if they may have had high productivity or income, the social investment in their medical education would have been underutilized. As it turned out, most of these jobs required a lower level of training than medical care.

3. Quantitative Underemployment: Our analysis identified a cluster formed by physicians who provided patient care, but did so under one or more negative circumstances suggesting that their work potential was severely underutilized.[15] As shown in Table 2, doctors in this cluster saw very few patients (the mean for the cluster was 18.2 patients per week, compared to 66.1 among all other physicians in patient care), worked reduced hours (a mean of 31.9 hours, compared to 55.3 among the rest of physicians, with 60 percent of underemployed doctors working less than 35 hours per week), and/or earned a low income (54 percent made less than three minimum wages, compared to 18 percent among fully employed doctors). In addition, these physicians tended to have unstable working conditions, characterized by job insecurity and high turnover rates.

4. Salaried Single Medical Employment: This is a conventional pattern composed of doctors with one stable salaried job in a health care organization, most often in the public sector.

5. Independent Single Medical Employment: This cluster represents another conventional pattern, wherein physicians work full time in their own private practices. In terms of income, this was a more heterogeneous cluster than the previous one; as shown in Table 2, the percentages in the lower end of the distribution were similar among both clusters with single employment, but independent doctors exhibited a much higher proportion of high-income earners. Such heterogeneity also accounts for the smaller average produc-

TABLE 2—Average Productivity and Income for Medical Employment Patterns Involving Patient Care

Medical Employment Patterns Involving Patient Care	Productivity: Mean number of patients seen per week	Productivity: Mean number of hours worked per week	Income: Percentage earning less than 3 minimum wages	Income: Percentage earning more than 5 minimum wages

Cramer's V	0.45		0.29		0.13			0.26			0.32					

tivity, since competition probably forces some independent physicians into the lower end of the distribution.

6. *Multiple Medical Employment:* This last pattern included cases holding two or more medical positions, the majority of them with one salaried and one independent job. In the Mexican medical labor market, as in many other developing countries, such a dual pattern has been traditionally considered to be very desirable, since it allows the physician to combine the prestige of a position in a public hospital with the economic incentives of a private practice. The advantages of this situation can be appreciated in the productivity and income figures presented in Table 2.

Analysis

The purposes of the analysis were to measure the frequency of each medical employment pattern, to determine the links among the variables, and to compare the relative strength of each relationship. In order to achieve this last purpose, we used percentage differences, as well as two conventional measures of association for cross-tabulations, namely, Cramer's V when the measurement level of the variables was nominal and Gamma when it was ordinal.[16–18]

Results

Table 3 presents a set of cross-tabulations between pairs of variables. The marginal totals provide the frequency distribution of employment patterns, and the percentages can be interpreted as employment rates. Thus, the unemployment rate is 7 percent, while the global underemployment rate (quantitative and qualitative) is 22 percent. Projecting these proportions, we can infer from the population of active physicians in the 16 cities (81,024) that un- and underemployment affect approximately 23,500 doctors.

Moving to the correlates of this problem, Table 3 indicates that all the explanatory variables, except social origin, exhibit significant and fairly strong overall associations with employment pattern. Beyond these common characteristics, it is worthwhile to examine each cross-tabulation.

Generation

Table 3 shows a marked increase in unemployment and underemployment from the oldest to the youngest group. Among those who do have a job, there is a shift from independent to salaried practice and from multiple to single employment. This variable reflects not only the intrinsic differences between the two generations, but also the different time spans that each group has been in the labor market. In addition, the sample may be biased for the older generation insofar as we only have the survivors. Nevertheless, the trends exhibited by our data are consistent with existing information about the supply and demand of physician manpower.

Gender

There is an important connection between generation and gender, since the proportion of women among physicians was 14 percent in the 1920–70 generation and 26 percent in 1971–86. As can be seen in Table 3, the proportion of unemployed women is three times higher than the corresponding figure for men. Although salaried single employment is the most important pattern for both groups, the second most important pattern is multiple employment among men and unemployment among women.

Social Origin

There is a tendency for multiple medical employment to be more frequent with higher social origin. Conversely, salaried single employment is not as important in the high group as it is in the other two, and unemployment is most frequent among physicians from the lowest socioeconomic background.

Medical School Quality

There is a marked descending gradient for the least desirable patterns as quality increases: 47 percent of physicians who studied at an inadequate school are un- or underemployed, compared to 24 percent and 17 percent of graduates from average and good schools, respectively. It is also worth noting that higher quality is associated with increasing proportions of multiple medical employment. This is the dominant pattern for physicians from the better schools, whereas salaried single employment is the most common pattern for inadequate and average schools.

Type of Specialty

Lack of postgraduate training greatly increases the chances of un- or underemployment: almost half of the physicians without a specialty are located in one of these categories. The practice of family medicine has become the prototype of medical work based on a single salary at the service of the state, with 83 percent of family doctors exhibiting such a pattern. The traditional pattern of multiple employment is now reserved for physicians with a basic specialty or a subspecialty, among whom unemployment is very rare.

Some of the effects shown in Table 3 could be indirect, as mediated by chronologically subsequent variables. In the case of gender, there were no significant differences between men and women in the quality of the medical school attended, but their respective opportunities for postgraduate training presented sharp contrasts. Thus, when specialty is examined by sex, we find that more than two-thirds of female doctors have no specialty, compared to less than half of their male colleagues (Table 4). Among those who do complete a residency, the proportions of men and women are about equal in family medicine. However, males dominate in the basic specialties and even more so in the subspecialties, where their proportion is twice that of females.

Social origin could also affect employment indirectly, through a relationship that is mediated by medical school. As shown in Table 5, the association between social origin and medical school is fairly strong. Thus, 40 percent of physicians from the lower social origin attended an inadequate medical school, compared with 44 percent of doctors from the higher social origin who went to a good school.

Part of the effect of medical school quality on employment may be mediated by type of speciality, since entrance to a residency is a competitive process that is bound to be affected by the quality of previous education. Table 6 demonstrates that there is a strong association between medical school quality and type of specialty. The likelihood of having no specialty increases consistently as quality decreases. Thus, the proportion of general practitioners is 1.4 and 2.2 times larger among graduates of inadequate schools than among doctors who studied at average or good schools, respectively. In contrast, good schools concentrate the highest proportions of basic specialists and subspecialists. In fact, we can consider the high degree of consistency of this association as a confirmation of the validity of our measure of school quality.

Discussion

The results of this study point to a series of imbalances, inadequacies, and inequities that characterize the medical labor market in Mexico. First of all, the heavy burden on Mexican society: almost one-third of all physicians living in the 16 major cities are unemployed or underemployed. Because these extreme forms of imbalance are likely to be concentrated in the large cities, the situation probably approaches the total for the whole country. In any event, the figure of 23,500 unemployed and underemployed physicians acquires its precise meaning when one considers that in 1986, the year when our survey was conducted, 9.3 million people, representing 11 percent of the Mexican population, did not have ready access to health services.[19]

TABLE 4—Type of Specialty by Gender

Type of Specialty	Gender Female %	 Male %
Without specialty	69	49

Basic specialties	11	20
Subspecialties	11	23
Total	100	100
N	100	391

$X^2 = 14.56$ $p = 0.0022$ Gamma = 0.36

Not all types of imbalance produce the same social impact. Unemployment and qualitative underemployment represent a waste of resources for society and a source of frustration for those doctors who have to work outside medicine or cannot find a job at all. Paradoxically, even those who are unemployed seem unwilling to serve in deprived rural areas, indicating that they would rather remain in the cities than be fully employed as physicians where their services are most needed.[20]

While unemployment and qualitative underemployment are undoubtedly severe problems, quantitative underemployment opens up a new perspective on physician oversupply. In this case, doctors still provide patient care, but do so at low levels of productivity. It is not unreasonable to assume that such doctors may represent a potential risk to their patients. Our analysis indicates that physicians with

low output tend to be young, have no postgraduate training, and often work in independent practices without any supervision. Under these circumstances, the quality of care may suffer through two mechanisms: first, doctors who see few patients may be unable to build up enough clinical experience; second, there may be a tendency to overprescribe medical procedures in order to derive a living from those few patients. The extent to which quantitative underemployment of doctors may represent a health risk is a subject for future research.

The appearance of imbalances also suggests that the medical labor market is experiencing a process of segmentation.[21] Apart from those physicians who are out of a medical job, there seem to be two major segments. The first one is characterized by reasonable productivity, relatively sufficient earnings, and stable employment conditions through a salaried position in government, a conventional private practice, or both. Diverging from the mainstream, a substantial number of doctors have entered into a marginal segment of the market, which is characterized by low productivity, insufficient earnings, and occupational instability. The segmentation process even extends to those who have attained relatively good positions, as illustrated by the fact that the traditional prestigious pattern of combining a salaried position in the public sector with a private practice is now dominated by physicians with a basic specialty or a subspecialty; in contrast, family doctors exemplify a new kind of medical functionary, since the vast majority of them hold their only job at the service of the government.

These cleavages in the medical profession reflect a broader process leading the medical education and health care systems to reproduce, rather than ameliorate, pre-existing social inequalities. Such a process begins with the channeling of students from different social origins to medical schools of varying quality. Indeed, the data reported here have demonstrated that there is a substantial degree of social stratification among medical schools, thus corroborating the findings from a previous study.[22] In turn, the quality of the medical school affects the probability of doing a specialty residency, which has a direct effect on employment. To complete this logic, we can assume that underemployed physicians are more likely to care for people from the lower social classes. There are reasons to believe that the quality of the care provided by these physicians is inadequate. In addition, there is empirical evidence that the distribution of the quality of care in Mexico is highly stratified by social class.[23] A circle is therefore closed: disadvantaged people will attend substandard medical schools and end up providing inferior care for other disadvantaged people. Obviously, this is not a deterministic but a probabilistic sequence of events. Indeed, we are not dealing with a rigid social structure that prescribes these patterns of behavior, but with one that tends to reproduce inequality. Although many individuals can and do escape from this vicious cycle, its existence seriously threatens the legitimacy of higher education and of health care.

The distribution of employment patterns by gender also exhibits important elements of inequality. In contrast to social origin, there is no stratification of medical schools by gender. Yet disparities are found in the opportunities for postgraduate residency, as shown by our data. Most of the substantial gender differentials in employment patterns can be attributed to the mediating effect of access to residencies. Such differentials acquire additional importance when one considers that the proportion of women in the medical profession is increasing. For example, by 1985 women constituted half the entering class at the most important medical school in the country, up from 38 percent in 1979.[24]

Despite their many sobering implications, our findings still leave ample room for policy interventions to correct imbalances. Many of the effects on employment appear to be mediated by the quality of medical schools and the opportunities for postgraduate training. Thus, actions can be implemented to improve inadequate schools and to make admissions dependent on academic potential only and not on the economic status of the student's family. Similarly, residency programs can adopt affirmative action measures that give women equal opportunities based solely on qualifications. In particular, it seems necessary to provide support services that will make the pursuit of a medical career compatible with other social roles.

With respect to those physicians who are already un- or underemployed, it would seem urgent to adopt continuing education programs that may compensate deficiencies in previous training and encourage those physicians to serve in rural areas. Such educational endeavors would have to be complemented by specific incentives, both in monetary terms and in opportunities for future career advancement. The ultimate obligation of protecting the health of the population also makes it necessary to consider mechanisms for the periodic certification of medical competence.

Finally, current effects to restrict the growth of medical schools must continue. Indeed, there can be little doubt that an overabundance of physicians has dysfunctional consequences not only for the medical profession itself, but also for the health system as a whole, including the users of services.

Above all, countries like Mexico must make explicit efforts to redress the inequities that still mar the systems of higher education and health care. The French sociologist Raymond Boudon spoke of "perverse effects" as an analytic category that accounts for the actual functioning of many social institutions.[25] Higher education and health care, two of the fundamental vehicles for promoting equity, are at risk of falling into the perverse effect of reproducing social inequalities. Unless they truly fulfill their role of ameliorating the negative consequences of poverty, they may themselves end up being impoverished institutions. The challenge, in essence, is to harmonize the legitimate aspirations for social advancement through higher education with the imperative of improving the well-being of the population. ☐

Acknowledgments

We are grateful to the following people: Begoña Artaloitia and Alfredo Hernández for their help in the analysis of the data; Armando Arredondo for his participation in the field work; José Luis Bobadilla for his advice on the definition of the research strategy; Luis Durán-Arenas for his contributions to the interpretation of the findings; Lilia Durán and José Becerra for their assistance in constructing the employment patterns; Héctor Hernández-Llamas, Miguel Cervera, Mercedes Pedrero, and Edmundo Berumen for their orientation regarding the survey design; Ronald Kessler, Rashid Bashshur, and Carlos Santos-Burgoa for their comments on the manuscript. The National Institute of Statistics, Geography, and Informatics generously gave us access to the primary source of data for our study. This research was funded in part with grants from the Pan American Health Organization, the National Council for Science and Technology of Mexico, and the Mexican Foundation for Health. While we greatly appreciate these various sources of support, the content of this article remains the sole responsibility of the authors.

Why Do Child Mortality Rates Fall? An Analysis of the Nicaraguan Experience

ABSTRACT

A comprehensive review of available sources of mortality data was undertaken to document the changes that have occurred in infant mortality in Nicaragua over the last three decades. It was found that a rapid fall in infant mortality commenced in the early 1970s and has continued steadily since. Trends in several different factors which might have led to this breakthrough were examined including: income, nutrition, breastfeeding practices, maternal education, immunizations, access to health services, provision of water supplies and sanitation, and anti-malarial programs. Of these, improved access to health services appears to have been the most important factor. At a time when the number of hospital beds per capita was dropping, increasing numbers of health care professionals, particularly nurses, were becoming available to staff primary health care facilities built in the 1960s. These were provided at least partly in response to the growing political turmoil enveloping the nation at that time. Certain Nicaraguan cultural attributes may have added to the impact of the reforms. Efforts in the field of public health made since the 1979 insurrection appear to have maintained the decline in child mortality. (*Am J Public Health* 1991; 81:30–37)

Introduction

Poor child health in developing countries continues to be a source of concern.[1] In recent years it has become apparent that while poverty is probably the major factor affecting survival in the early years of life, there are undoubtedly other influences playing an important role. Some countries, in spite of a low per capita gross national product, have succeeded in achieving mortality levels close or equal to those of the industrialized world. In contrast, there are others with poor levels of child health despite enjoying relatively high per capita incomes.[2] Efforts have recently been made to identify the factors beside socioeconomic status which are determinants of infant mortality. In 1985, the Rockefeller Foundation sponsored a conference which studied the striking mortality reductions in Kerala State (India), Sri Lanka, Costa Rica, and China.[3] In each case, mortality has fallen sharply over a relatively short period leading to high life expectancy relative to national income. Seven conditions were purported to be essential to the observed improvements: female autonomy, education (especially female), the provision of accessible health services, a mechanism to guarantee the efficient operation of health services, an adequate minimal standard of nutrition, universal immunization, and a commitment to the establishment of effective antenatal and obstetric services.[2]

Nicaragua is another country which has experienced a recent breakthrough in child mortality. This article describes that breakthrough and looks at its relationship with some of the factors alleged to be important determinants of child mortality. It is hoped this work serve as a model for the type of intersectoral data analysis advocated recently by de Kadt.[4]

Methods

Seven different sources of data were identified which could provide time-located estimates of infant mortality in Nicaragua from 1960 to 1986.[5–11] A brief description of each source of data is given in the Appendix. Except for data obtained from the Civil Register, the infant mortality estimates were derived using the Brass technique based on the ratio of surviving to ever born children of mothers classified by five-year age group. The rationale behind this method is that the proportions dead of ever born children for women of a certain age correspond to discreet child survival probabilities. These survival probabilities can be used to calculate infant mortality rates (IMRs) if one assumes a typical age pattern of mortality. In this case the Coale-Demeny 'West' model of mortality was used.[12]

Variations of the Brass method have been developed which allow the estimation of trends in mortality change, recognizing that the deaths in children born to

FIGURE 1—The trend in Nicaraguan infant mortality by data source, 1956–86

women ages 15–19 years have occurred more recently than the deaths in children of women ages 45–49. The Trussell method, which was employed in this analysis is one such variant.[13] It provides time locations for the infant mortality estimates obtained from each five-year age group of mothers.

Estimates of infant mortality from the death register were calculated by dividing the number of deaths registered in each year by the projected population under the age of one. Death registration is well known to be variable and incomplete so these figures were not used in further calculations. However, the relatively low rate of omission for birth registration allows a more accurate estimation of the IMR by asking about the survival of preceding births at the time of registration. The data for 1986 (SINEVI-86) were analyzed in this way by the Centro Latino-Americano de Demografía (CELADE).[11]

There are a number of factors which are believed to be important determinants of child mortality. These include: income, nutrition, maternal education, breastfeeding, immunization coverage, the provision of health services, access to water supplies and sanitation, malaria control, as well as certain cultural attributes of the population. Trends in these factors were examined and related to the observed changes in infant mortality in Nicaragua from 1960 to 1989. Wherever possible, data were obtained from the original sources in Nicaragua by visiting libraries and documentation centers in government ministries and institutions.

Data on per capita Gross National Product (GNP) were obtained from an analysis performed by the National Autonomous University of Nicaragua.[14] It was not possible to accurately quantify changes in income distribution.

An assessment of trends in child nutritional status was based on three surveys on nationwide samples of children in 1966, 1977–8, and 1986.[15–17] Height for age was used as the indicator of nutritional status as it was the only one measured in all three surveys. In two of the surveys,[15,16] the children measured were under the age of 5, in the third they were school children ages 6–9 years. Figures for food production and caloric intake were derived from World Bank[18] and United Nations Food and Agricultural Organization[19] statistics, respectively. The frequency of breastfeeding in 1977 and 1988 was estimated from two ad hoc surveys performed in Managua.[20,21]

Levels of illiteracy in Nicaragua were obtained from the censuses of 1950,[22] 1963,[23] and 1971[5] and from the EDENIC-78 and ESDENIC-85 surveys.[11] Rates were calculated for the total population ages 10 years and over, for the urban and rural populations, and for women ages 15–44 years.

An analysis of Ministry of Health cause of death statistics by CELADE documents changes in death rates in children due to immuno-preventable diseases.[11] These were compared with an indicator of vaccination coverage, estimated by dividing the Ministry of Health figures for the annual number of inoculations by the population of children under the age of five for that year.

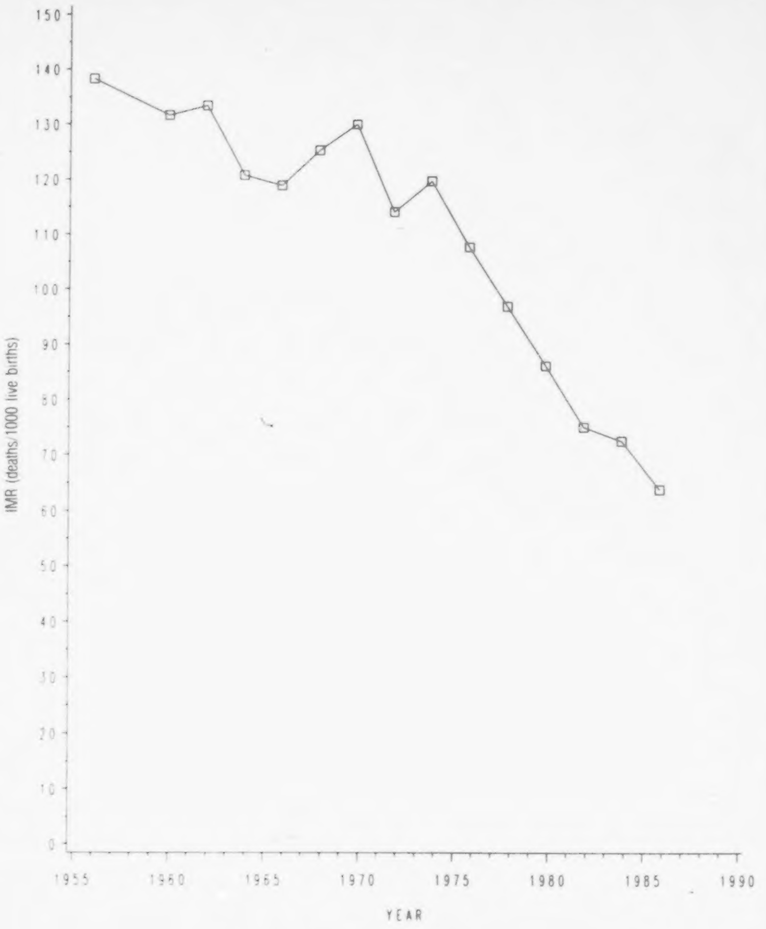
There have been several analyses of Nicaragua's health system, mostly comparing the situation before and after the 1979 insurrection.[24–27] These were reviewed and combined with statistics from the health sector[10,28–30] (public and private) to obtain an overview of the trends in the provision of health services—both as infrastructure and as human resources—from 1960 to 1985.

National statistics were used to determine what changes had taken place in domestic water supply and sanitation facilities.[10,30] Figures for latrine construction were taken from Ministry of Health records.[28] An analysis by Garfield and Vermund[31] and national records of laboratory tests for malaria were used to look at trends in the incidence of malaria.

Results

Infant Mortality Estimates

Figure 1 shows the infant mortality estimates from each of the aforemen-



Sources: Census 1971, EDENIC-78, ESDENIC-85, SINEVI-86, Sentinel Sites 1988

FIGURE 2—The trend in Nicaraguan infant mortality: 1956–86 (weighted averages)

tioned sources plotted against time. Estimates from ESDENIC-85, SINEVI-86 and the 1971 Census, the three largest databases, give a consistent profile of the trend in mortality. Moreover, the IMRs from the sentinel sites study agree remarkably well with those of ESDENIC-85. There is some divergence in the mortality estimates from EDENIC-78, particularly for the early 1970s but these are based on data from a small number of women and hence this may be due to sampling error. The rates calculated from death registration are incompatible with the other estimates, a reflection of gross inadequacies in coverage of this system. They are not used in further analyses.

A weighted average of infant mortality estimates from the 1971 census, the EDENIC-78 and ESDENIC-85 surveys, the SINEVI-86 analysis of birth registration and the sentinel sites study was made for each two-year interval. Rates obtained from women ages 15–19 years were not included as these are well known to be unreliable.[13] The results are plotted in Figure 2. Figure 3 presents the same data plotted on a logarithmic scale which more appropriately portrays the change in the rate of decline. Taken as a whole, the studies indicate that the rate of fall in infant mortality, which was slow in the 1960s, increased sharply in the early 1970s, and that this rapid decline was still continuing in 1986. The infant mortality rate drops on average by 4.7 deaths per 1,000 live births for each year from 1974 to 1986. Assuming a 'West' mortality schedule, this is equivalent to an annual increase in life expectancy of 0.75 years each year over this 12-year period.

Figure 4 presents urban and rural IMRs from the 1971 Census and ESDENIC-85. Changes in the definitions of 'urban' and 'rural' and internal migration make interpretation difficult but there is no clear evidence that in Nicaragua the breakthrough was more pronounced in rural areas than in urban areas.

Differential infant mortality rates according to levels of maternal education are provided by the CELADE analysis. In the three time periods examined—1966–67, 1973–74, and 1982–83—infant mortality rates for mothers with secondary or higher education were considerably lower than for mothers with primary or no formal education. The results suggested that this differential narrowed over the period in question (data not shown).

Explanations for the Decline in Child Mortality

How can this sharp drop in child mortality be explained? In the first place, it should be recognized that more than one factor may be involved. The reason that mortality started to fall may be different from the reason that it continues to fall. Since this is not a controlled experiment, causes can easily be confused with effects, and one is always left in doubt as to what would have happened in a different set of circumstances. Nevertheless, the Nicaraguan case has some very interesting features which make it worth examining in greater detail.

Income—The observed infant mortality decline in Nicaragua does not correspond to a rise in general living standards. Per capita GNP rose rapidly in the early 1960s but flattened off in the 1970s before falling sharply in the 1980s. This fall may have been offset somewhat by a more equal distribution of wealth following the insurrection (as a result of the wages policy, food subsidies and rationing, price controls, and rent controls), but there are insufficient data to quantify changes in income distribution over this period.

Nutrition—In 1966, 36 percent of children under the age of 5 were found to be below two standard deviations in the reference range for height for age. In the survey performed from 1977 to 1978, 26 percent of children under the age of 5 were below two standard deviations for height for age and in 1986 the corresponding prevalence of stunting in first grade school children (ages 6–9 years) was 22 percent. Although Nicaragua has high rates of primary school attendance, poor children tend to start later than the rest. This produced an age bias in the results of the 1986 survey such that in 6-year-old first grade children the prevalence of low height for

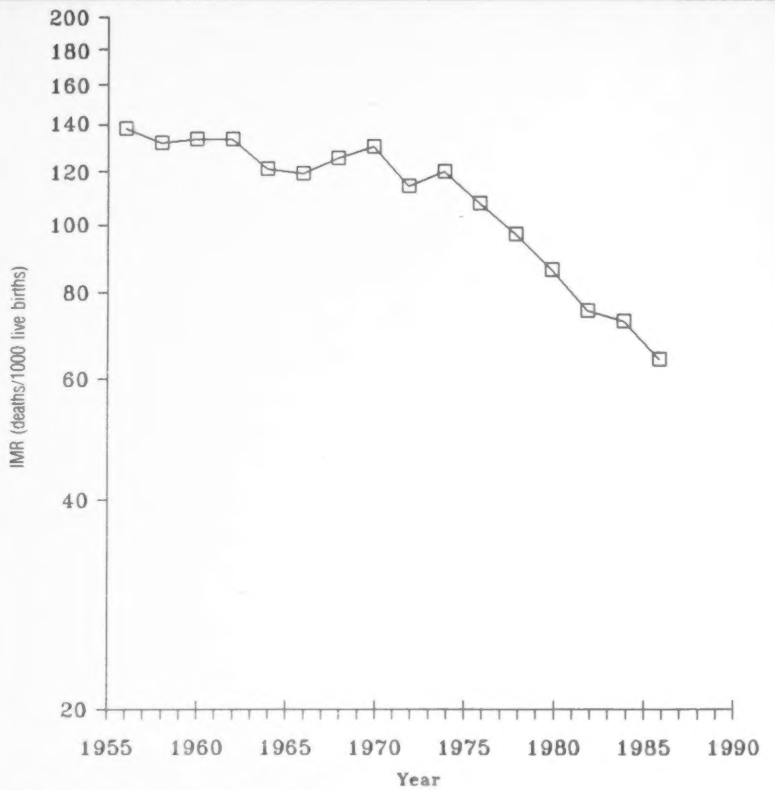


FIGURE 3—The trend in Nicaraguan infant mortality: 1956–86 (weighted averages) plotted on a logarithmic scale (base 10)

age was only 14.5 percent compared with 32.7 percent for 9-year-old first grade pupils.

Despite the deficiencies in the available data, it would seem reasonable to conclude that nutritional status in Nicaraguan children improved steadily from 1966 to 1986, but the factors leading to this improvement are uncertain. Food production in 1986 was only 70 percent of what it was in 1967 having fallen sharply from its peak in 1978. The number of food calories per head of population dropped from 2,410 in 1970 to 2,344 in 1975 and then to 2,258 in 1980, recovering slightly by 1983 to 2,304.

On the other hand, a variety of programs and activities aimed at improving child nutrition already existed in 1970.[32] These were expanded in 1973 in response to the threat posed by the 1971 drought and the 1972 earthquake. A milk distribution program of the Ministry of Public Health was in operation since the 1960s but was gradually abandoned in the late 1970s. It was recommended for several years following the 1979 insurrection along with other policies aimed at establishing an adequate nutritional standard. These included food subsidies, rationing, and supplementary feeding programs for pregnant women and malnourished children.

Breastfeeding—The limited data available suggest that there has been no increase, and perhaps a decrease occurred in the average duration of breastfeeding in Nicaragua over the period of rapidly declining child mortality. In 1977, 58 percent of mothers in Managua were breastfeeding their children for at least six months. In 1988, only 33 percent of children between three and five months of age were still receiving breast milk.

Maternal Education—The changes in the rate of illiteracy in Nicaragua are summarized in Table 1. The tendency has been for illiteracy to decrease throughout the period from 1950 to 1985. The overall drop in illiteracy is greater than the individual falls in urban and rural areas because of migration to the town and cities. The slowest rate of change in the overall prevalence of illiteracy was observed between 1971 and 1978. Between 1978 and 1985 there was a marked drop in the prevalence of illiteracy, mainly as a consequence of the 1980 National Literacy Crusade and the extensive adult education program which followed.

Immunizations—Mortality due to diseases preventable by immunization in the ages 1–4 dropped from 21 per 10,000 in 1975 to 3 per 10,000 in 1986 (or from 17 percent to 4 percent as a proportion of total mortality in this age group). Unfortunately, the poor quality of the statistics did not permit a similar analysis for children under one year of age.

Table 2 shows the change in rates of immunization over the period from 1970 to 1985. Prior to 1979 rates of vaccination coverage varied widely as periodic campaigns were launched in response to cyclic epidemics of immuno-preventable disease. Since 1979 coverage has been higher and shown less variation. The participation in massive nationwide vaccination campaigns of large numbers of voluntary health workers in the years immediately following the insurrection was probably the main factor in this improvement.

Health Services—In comparison with other developing countries, Nicaragua's health system suffered more from maldistribution of resources than from a lack of investment. Health service infrastructure and personnel were concentrated in the cities and particularly in the capital. In the 1960s and 1970s, efforts were made to redress this imbalance and improve access to health care. A USAID loan of $US 2.2 million was received in 1965 to set up 55 health centers and provide outreach programs in rural areas. By 1974 there were 33 hospitals, 93 health centers and 38 health posts spread throughout the country, and the Rural Mobile Health Program provided care to remote areas. More primary health care facilities were built in the first years following the insurrection.

Although considerable infrastructure was already installed by 1973, an evaluation of the 55 health centers built from USAID loan found low utilization rates owing to the lack of personnel, supplies, and management support. Two further USAID grants were made in the mid-1970s to correct these deficiencies.

In contrast to the growth in primary health care facilities, there was a general deterioration in hospital care since the early 1970s. The number of hospital beds per capita peaked at 2.6 in 1971 and has gradually dropped since. The National Social Security Institute (INSS), a health care provider, grew slowly but steadily from 1960 to 1980. In 1963, only 4.1 per-

cent of the population were insured. By 1971 coverage of the population had increased to 7.5 percent and by 1978 to 8.4 percent. In 1980 under the Government of National Reconstruction, coverage reached 10.1 percent of the population.

The number of doctors and especially nurses per head of population increased between 1974 to 1985. From 1970–74, there were 5.4 doctors and 2.3 nurses per 10,000 inhabitants. For the period 1975–79 there were 5.8 doctors and 2.6 nurses per 10,000 population and in the five years from 1980–84 there was an average of 6.0 doctors and 3.3 nurses per 10,000 population. The impact of the increased availability of health care professionals (together with dropping numbers of hospital beds per head of population) was reflected in rising per capita rates of hospital discharge and rapidly increasing numbers of outpatient consultations (especially emergency consultations).

Other Public Health Measures—Nicaragua undoubtedly had low rates of access to plentiful clean water supplies and sanitation prior to 1974, but the situation has changed little since then. In 1981, the number of urban domiciliary connections was almost identical to that prior to the earthquake in 1972. Latrine construction by the Ministry of Health, which averaged 4,590 per year from 1974–78, was barely sufficient to keep up with the increase in the rural population.

The use of residual insecticides for the control of malaria decreased steadily in the late 1970s as the World Health Organization campaign for the elimination of malaria lost its momentum. The number of notified cases varied widely from one year to the next but showed no secular downward trend from 1972–82. The average annual reported number of laboratory confirmed cases was 15,386 from 1972–76 and 18,738 from 1977–81. A renewed effort was made to control malaria in 1981 by the administration of mass chemoprophylaxis but the impact was transient.

Discussion

From a variety of sources of infant mortality estimates, this paper has documented a rapid decline in infant mortality in Nicaragua which commenced in about 1974 and was still in progress in 1986. The rate of decline since 1974 is impressive, particularly considering that it occurred at a time when the mortality decline in most countries in Asia, Africa, and Latin America was slowing down.[33] The rate of improvement in life expectancy is similar to that experienced by either Costa Rica (at 0.70/year) and Kerala State (at 0.80/year) during their respective periods of rapid mortality decline, but is not as high as Sri Lanka's (at 1.7/year).[2]

Much work on the determinants of reductions in child mortality has focused upon economic factors. It has often been difficult to separate the role of health and other social interventions from general economic progress, since changes have occurred in parallel. In Nicaragua, this was not the case as the sharp drop in child mortality took place at a time when the

TABLE 2—Average Number of Vaccines Administered per Child under the Age of Five

Years	DPT	Polio	BCG
1970–75	0.59	1.02	0.21
1976–80	0.48	1.24	0.17
1981–85	0.99	2.66	0.33

general living standards of the population, measured in terms of per capita national income, actually decreased.

Although there was some improvement in the nutritional status of Nicaraguan children between 1966 and 1988, this was probably more due to a reduced burden of infectious illness than to increased food intake. The factors which led to a drop in the incidence, severity or duration of infection may be the same as those which brought about lower child mortality. It is difficult to follow breastfeeding practice over the last 20 years but it does seem that exclusive breastfeeding is still far from the norm for a variety of reasons.[34] While health education materials were concerned with promoting breastfeeding, the free milk provided by Ministry of Health programs before and after the insurrection may have encouraged mothers to abandon the practice.

The 1974 turning point in child mortality does not appear to have been brought about by a sudden increase in levels of female literacy, although this factor may have contributed to more recent falls in child mortality. Similarly, most of the reduction in mortality due to diseases preventable by vaccination probably occurred some time in the early 1980s and does not coincide with the onset of the decline in child mortality.

The introduction of oral rehydration therapy (ORT) for the management of diarrhea did not occur until the middle of the period of rapidly declining mortality. The Ministry of Health's plan for 1976–80[35] does not even mention ORT, and it was not until 1980 that oral dehydration units were established in health centers and health posts.

The results of this investigation suggest that the availability of water supply and sanitation did not improve significantly from 1974–86. Any improvement in malaria control is unlikely to have been sufficiently great to account for the decline in infant mortality given that malaria is not a major cause of death in this age group in Nicaragua.[36]

The most plausible explanation for the onset in 1974 of Nicaragua's rapid decline in infant mortality can be found in the changes in health services which started to take place at that time. The combined impact of declining per capita numbers of hospitals beds with increasing numbers of health care professionals meant greater availability of personnel to work in the understaffed clinics which had been built in the 1960s. In other words, there was in effect a sharp shift in resources away from hospitals and towards primary and secondary health care. Figure 5 shows how the number of hospital beds per health professional dropped sharply in 1972 and showed a tendency to decrease until at least 1984, parallel to the infant mortality decline.

The reason for this sudden shift in the nature of health care in Nicaragua is complex. The decreasing availability of hospital beds was due to a combination of the devastation resulting from the earthquake, the war, rapid population growth, and economic constraints to public spending. Training of health care professionals, on the other hand, surpassed the increase in population.

Political influences have no doubt also played a part in this situation. The decline and fall of Somoza has been dated from the 1972 earthquake[24,37] and political turmoil has been the norm ever since. A mass popular movement grew up in the late 1970s culminating in the 1979 insurrection. Perhaps sensing that the ground was slipping out from beneath him, Somoza with United States aid began to make significant invest-

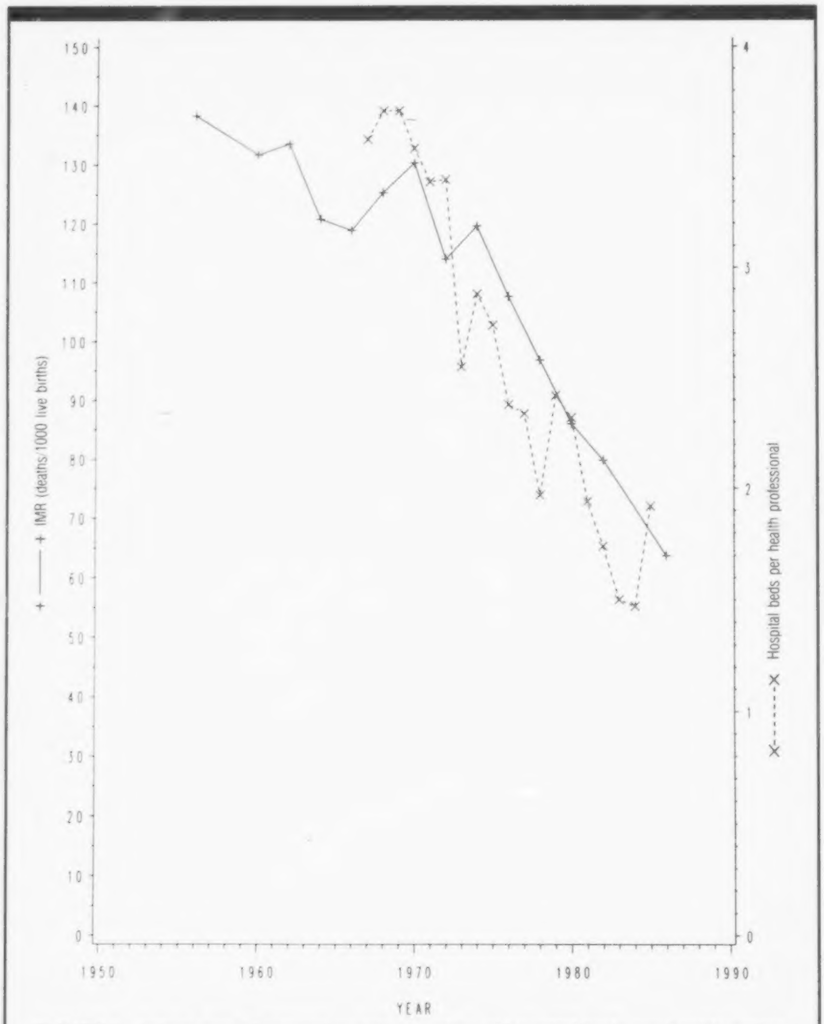

FIGURE 5—Infant mortality trend and the number of hospital beds per health professional in Nicaragua, 1956–86

The solid line is IMR.
The broken line is hospital beds.

ment in social programs. In these programs the government tried to target areas with major guerilla activity.[24]

In post-revolutionary Nicaragua, political factors have been equally important. The Sandinista National Liberation Front took power on a program in which health and education were key components.[38] In President Ortega's speech on the 10th anniversary of the Nicaraguan Revolution, reductions in rates of illiteracy and infant mortality were the first items held up as gains of the revolution.[39]

Cultural factors may also have been important. Although tradition changes too slowly to explain a sudden reduction in mortality of the sort experienced by Nicaragua, certain cultural attributes facilitate rapid reductions in mortality. Primary health care programs can have little impact without appropriate patterns of health-seeking behavior. In Nicaragua, there exists what has been described as a pill culture.[40] People regard orthodox medicine and its providers (i.e. doctors and nurses) with high esteem. Manufactured pharmaceuticals, particularly when given by injection, are generally preferred to traditional herbal remedies although often both will be employed. Nicaraguans readily change treatments when a rapid improvement is not seen and are highly sensitive to the progress of illness in their children. As a result, when health services became more generally available in the 1970s and 1980s, the population quickly made use of them.

It is interesting to compare Nicaragua's period of rapid mortality decline with that of neighboring Costa Rica which also occurred during the early 1970s.[41,42] Both countries had experienced a slow rate of improvement during the 1960s—a phenomenon common to many developing countries.[33] In Costa Rica, the drop in infant mortality was greater in rural areas than in urban areas, both in relative and absolute terms. An analysis of Costa Rica's recent decline in infant mortality also shows up the singular importance of primary health care.[42]

Having reviewed the available data, it is possible to postulate the following scenario. In the late 1960s United States aid was used to pay for the construction of primary health care facilities throughout Nicaragua. In the 1970s, earthquake, war, rapid population growth and economic recession reduced the number of hospital beds per capita. At the same time there was an increase in the supply of nurses and doctors per head of population which made it possible to staff the recently built primary health care facilities. The net effect was an increase in the relative importance of primary and secondary health care vis a vis tertiary health care. The health care facilities provided gained rapid acceptance from the population which already had some cultural affinity for Western medicine.

The social reforms contributing to declining child mortality were made by an isolated and threatened dictatorship in response to the mobilization of impoverished sectors of society. They were continued and extended following the insurrection, as part of the political program of the Sandinista Government which replaced the dictatorship. In early 1990, a new government was elected which is committed to contraction of public expenditure. Monitoring the effects of any change in policy on child health and survival will provide an opportunity to ex-

APPENDIX—Sources of Infant Mortality Statistics in Nicaragua

A review was performed to identify the various sources of data on national child mortality rates in Nicaragua from 1960 to 1989. These are shown in Table A. A note of explanation is necessary about each of the data bases.

The 1971 Census

The last national census of Nicaragua took place on April 20, 1971. Since then, war and lack of funding have prevented the government from carrying out another population census. The 1971 census registered a total population of 1,878,000. The overall rate of omission is thought to be 6.3 percent but in 19 of the 126 municipalities there was an average omission rate of 32 percent and in a further 18 municipalities the rate was 22 percent.[5] An experimental census was carried out in 1969 as a prelude to the 1971 census but its sample was small and unrepresentative of the entire population so the results are not presented here.[43]

The National Demographic Survey of Nicaragua (EDENIC-78)

This was a survey carried out from 1977 to 1978 which included retrospective questions for indirect mortality estimation. It was a follow-up study in which it was intended to compare indirect estimations of mortality with prospective estimates derived from the household change technique. Unfortunately, during the 1979 insurrection all of the prospective data from this survey were lost, leaving only the retrospective questions for mortality estimation. Some of the retrospective data were also lost. The Atlantic Coast Departments of Zelaya and Rio San Juan were excluded from the sampling frame. Although the infant mortality rate in this area is probably higher than in the rest of Nicaragua, it is inhabited by only 8.6 percent of the population.

The Sociodemographic Survey of Nicaragua (ESDENIC-85)

This large household survey took place in 1985, aiming to generate up-to-date demographic and socioeconomic information for the whole country, given that the census planned for 1982 had been suspended. Technical assistance was provided by CELADE and the United Nations Department of Technical Cooperation for Development.[44]

A pilot test in 535 homes was performed in September 1984 and definitive data collection commenced in July 1985. In contrast to EDENIC-78 which excluded the Atlantic Coast, the reference population of ESDENIC-85 covered the entire country. A two-stage cluster sample of 18,000 homes was chosen.

The Sentinel Sites Study

In 1986 the Ministry of Health (MINSA) in collaboration with consultants from UNICEF, established a set of 34 sentinel sites in three regions of the country.[9] These were intended to provide accurate population-based data on morbidity, mortality, and health service utilization for planners and administrators. The sentinel sites were selected by regional teams on the grounds that they be representative of the health conditions of their region. Data were collected by household survey with indirect questions on child mortality.

The National System of Vital Statistics (SINEVI)

In the 1960s, the civil register was administered by the Directorate General of Statistics and Censuses which was part of the Ministry of Economy. In 1970 the DGEC merged with the Department of Economic Studies of the Central Bank to form the Executive Office of Surveys and Censuses (OEDEC). Vital events were registered in the Offices of the Civil Register in each municipality. The data were published annually in the Statistical Yearbook. Coverage was estimated at 70 percent for births and 30 percent for deaths. Only 48 percent of registered deaths were certified by a doctor. The Ministry of Health was responsible for processing cause-specific mortality rates which were not published in Nicaragua but were sent to the World Health Organization.[45]

When the new government took power in 1979, several changes were introduced to improve the registration of vital statistics but, despite these measures, serious deficiencies in death registration remain. In 1987, overall coverage was estimated at 47 percent,[36] but only about 34 percent of infant deaths are reported.[11] Birth registration is somewhat better; in 1983 coverage was calculated to be somewhere between 79.3 and 86.5 percent, varying from less than 60 percent in the rural population to about 95 percent in the urban population.[46]

TABLE A—Sources of Infant Mortality Statistics in Nicaragua

Date	Data Source	Type of Data	No. Women Ages 15–34	Regional Coverage[a] %
1971	National census[6,7]	Population census	256,907	100
1978	EDENIC-78[8]	Sample survey	6,237	91
1985	ESDENIC-85[9]	Sample survey	22,000[b]	100
1986–88	Sentinel sites[10]	Sentinel sites survey	9,615	54
1956–86	SINEVI[11]	Death registration	—	100
1986	SINEVI-86[12]	Birth registration	112,200[b]	100

The Role of Attitudes, Beliefs, and Personal Characteristics of Italian Physicians in the Surgical Treatment of Early Breast Cancer

ABSTRACT

The influence of Italian physicians' attitudes, beliefs, and personal characteristics on medical decision making is examined in the case of surgical treatment of early breast cancer. Responses to a mail survey of 657 physicians from different specialties were analyzed comparing doctors recommending a radical procedure (9%) to those preferring a conservative procedure for younger patients only (25%), and those considering conservative surgery the treatment of choice regardless of patients' age (66%). The findings suggest that the likelihood of physicians' preferring a conservative procedure is influenced by their specialty and the extent to which they feel that a patient should have a role in the treatment decision more than by differences in the beliefs of treatment outcomes. Only preferences of the small group indicating radical surgery as the sole admissible treatment can be accounted for by ignorance or distrust of results of recent trials. These findings suggest that other than scientific factors guide many doctors in their decision making; they may help to explain why the diffusion of research results into clinical practice is often disappointingly slow. (*Am J Public Health* 1991; 81:38–42)

Introduction

The extent to which trial results influence clinical practice is a subject of growing interest and controversy. The roles of doctors' attitudes, belief and personal factors in this respect have seldom been directly assessed, however. The controversy on the optimal surgical treatment of early breast cancer is an excellent area for such an investigation. Despite the substantial body of evidence now available on the comparative efficacy of limited and radical surgery,[1–3] the acceptance of conservative procedures in general practice is slower than one could expect. Possible explanations offered include: ignorance of trial results; uncertainty in interpreting trial results[4–9]; the influence of personal or institutional-related factors.[10–12]

To shed light on the merits of these three related hypotheses, we undertook this study as part of a current research program aimed at assessing quality of care for breast cancer patients in general hospitals.[6]

Organization of Cancer Care in Italy

In Italy health care is provided largely free of charge with patients co-payment for a limited—though increasing—number of services. The national health service—launched in 1978—envisages a system where health care is provided through public facilities (approximately 1,000 general hospitals where about 40,000 doctors practice) or, indirectly, by contracting with private health providers. Relative to cancer care apart from patients seen at the few Italian cancer centers, most patients are cared for at public general hospitals. There is a great deal of variability in the type of existing organization within these hospitals: few are equipped with oncology departments staffed with board-certified oncologists; others—accounting for approximately 10 percent of the total—see patients in oncologic wards staffed by internists, surgeons, and radiotherapists with special interest in oncology; but the vast majority of hospitals have no ad hoc organization and patients are seen at different departments depending on their specific needs.

Methods

This study was conducted between October 1986–June 1987 on a sample of hospital-based physicians. Sixty hospitals taking part in an existing monitoring program on quality of cancer care were invited to participate, 65 percent agreed to do so. Participating and non-participating hospitals were similar in size (median number of beds of 888 and 870, respectively), and organization of cancer care (35 percent of both groups had radiotherapy on site and an oncology department was present in 20 percent and 30 percent of participating and non-participating cen-

ters, respectively). Six hundred and fifty-seven questionnaires were returned corresponding to an overall response rate of 68 percent (657/970), 20 percent of which were from physicians not seeing patients with breast cancer. Surgeons had a 60 percent response; internists 68 percent, gynecologists 74 percent, radiotherapists 84 percent and oncologists 89 percent. Participation tended to be slightly higher among younger (78 percent) and female (77 percent) physicians. An additional telephone inquiry was attempted on a randomly selected one-third of the 313 nonresponders. All were successfully traced and their responses were similar to those obtained by mail.

In the questionnaire, basic data were requested about the hospital in which physicians practiced and some personal characteristics. The first section of the questionnaire described four scenarios, two dealing with treatment of primary breast lesion and two dealing with adjuvant postsurgical treatment. In this paper we shall discuss the results relative to the surgical preferences. The first scenario was phrased as follows:

> A 35-year old premenopausal patient presents with a 1.5 cm. diameter mass in the upper outer quadrant of her right breast. Axillary lymph nodes are clinically negative and there are no other signs of metastases. Assuming that whatever blood test, X-ray examinations, and nuclear scans you use are negative and that a preliminary biopsy has established the diagnosis of carcinoma, do you favor a radical surgical approach or a breast-sparing operation (limited surgery) combined with primary radiotherapy? The radical surgical approach would mean a type of radical mastectomy (i.e. Halsted or Patey), while the limited surgery would involve a quadrantectomy, plus axillary dissection and radical radiotherapy.

After checking one of the two options (1 = I favor a radical surgery approach; 2 = I favor a limited surgery approach), responders rated the superiority of the alternative treatment modes in achieving the following outcomes: local control, disease-free survival, avoidance of morbidity, good cosmetic results, and long-term survival. A 5-point scale was used for each outcome: 1 = limited surgery plus irradiation is vastly superior to radical surgery; 5 = radical surgery is vastly superior to limited surgery plus irradiation; 3 = the two treatment modes are equally effective.

A second case presentation referred to an older patient (i.e. 60 years) with identical clinical information to see whether doctors deemed patient age a critical factor in treatment indication. The same treatment choices and efficacy judgment were required.

TABLE 1—Distribution of Physicians' Sociodemographic and Practice-related Characteristics according to Therapeutic Preferences

R = radical surgery regardless of patient's age;
C-R = conservative only in younger patients;
C = conservative surgery regardless of patient's age.
*Information not available in three cases.
**Information not available in nine cases.

In the second section, physicians were asked to comment on findings from a pattern of care study conducted in Italy in 1984 documenting that only approximately one out of four patients eligible for limited surgery actually had limited surgery.[6] Doctors were asked to report why in their opinion a radical procedure was still the preferred treatment option by choosing among a list of possible explanations reported into the questionnaire. A free text format was also included so that they could add other reasons if they were not satisfied by the list.

The final section of the questionnaire contained a series of statements designed to measure physicians' attitudes toward involving patients in treatment decisions. Responders indicated on 5-point scales the extent to which they agreed or disagreed with 10 phrases such as "asking patients to participate in treatment decisions produces unnecessary stress for them," or "patients who participate in treatment decisions are less anxious and depressed during recovery." Statements were worded so that, for some, agreement indicated attitudes favoring participation and, for others, an unfavorable attitude. The scale was similar to the one used in a previous study in the United States.[10]

Analysis of the role of physicians' willingness to involve patients in treatment decisions was done both by considering answers to individual statements and by analyzing the overall score based on the scale; the Kruskal-Wallis test was used for statistical analysis.[13] In the computation of this test, all of the scores from all samples combined are ranked. The sum of the ranks in each sample is found, and the test determines whether these sums of ranks are so disparate that they are not likely to have come from samples which were all drawn from the same population.[13] Results of this type of analysis are those reported in Table 2.

Results

Table 1 shows the distribution of physicians' sociodemographic and practice-related characteristics according to therapeutic preferences. Two-thirds felt that a conservative procedure was the appropriate treatment independently of patients' age; only 33 (9 percent) preferred the traditional radical procedure regardless of age. Almost all the radiotherapists favored the conservative procedure regardless of patients' age while more than one-fourth of doctors from other specialties deemed the conservative procedure appropriate only for younger patients. Surgeons and internists were more often supportive of the traditional radical technique.

A greater willingness to involve patients in the decision-making process was associated with preference for conservative surgery (Kruskal-Wallis test = p = 0.011 for difference in overall patient participation score among the three groups). Detailed analysis of physicians' answers to individual statements component of the overall score indicated that doctors recommending conservative surgery regardless of patient age (the "C" group in the tables) had a consistently different pattern of attitudes (see Table 2) compared to those indicating radical surgery as the optimal treatment.

Besides this marked difference in personal attitudes, the groups also dif[illegible] in their perceptions of the efficacy [illegible] and overall desirability of the two trea[illegible]ments (Table 3). Almost all doctors in favor of the more radical procedure (94 percent) thought it was superior in terms of local control, particularly for the older woman while doctors always favoring limited surgery most of time claimed comparable effectiveness of the two treatments in all but cosmetic results.

In the intermediate group (i.e. those preferring conservative surgery in the younger but radical in the older patient) the relationship between reported therapeutic preference on one side, and attitudes and beliefs about outcomes on the other, was less easy to interpret. Patients' age seemed, although to a limited extent, to influence perception of treatment effectiveness in this group. Physicians' answers were more like those of the radical

TABLE 2—Distribution of Scores (mean ranks) in Individual Statements Exploring Physicians' Willingness to Involve Patients in Treatment Decisions according to Therapeutic Preferences

Negatively worded statements	R	C-R	C	p value
	Mean Ranks			
Patients may lose confidence in their physician if they believe that he/she has no firm opinion about the best treatment	221.1	227.9	219.8	.80

group particularly with respect to the decision pattern for the older patient (Table 3).

As a whole, joint examination of the beliefs of the intermediate group (Table 3) and their willingness to involve patients in treatment decisions (Table 2) suggests that—independently of perceived treatment effectiveness—less consideration for patients' expectations was probably the factor influencing choice of a radical procedure for an older patient in whom negative cosmetic consequences were judged less important. This interpretation is supported indirectly considering the distribution of physicians' opinions of reasons why the diffusion of conservative surgery is still limited (Table 4). The majority in the radical group (42 percent) claimed conflicting trial results as the reason for this, but 34 percent of doctors in the conservative group felt that prevailing practice could be accounted for by surgeons' reluctance to accept trial results (Table 4).

Discussion

Decisions about alternative treatments involve implicit and explicit weighing of trade-offs among different outcomes (survival, morbidity, functional status, etc.). Our study suggests that beliefs about treatment outcomes derived from clinical trials are not always the most important factors in decisions for some doctors. This is not a new finding as other studies exploring determinants of physicians' practice[10–14] have found associations of specialty, age, and practice-related characteristics with practice patterns.

The grouping of doctors according to their therapeutic preferences is of particular interest for analyzing the consistency between perceived outcomes of treatment and the decision pattern. At one extreme, we found a small group (9 percent) whose therapeutic preference—although based on a miscomprehension, or non-acceptance, of recent scientific literature—was consistent with perceived outcomes of treatment: doctors chose a radical procedure because they thought it was more effective than limited surgery. If we take their answers as a true reflection of their opinions, and not as the result of a preference-dependent selection of that segment of the literature fitting their own preconceptions, exposure to the relevant scientific literature would be the appropriate remedial action.

At the other extreme, those choosing limited surgery appeared to be guided by the consideration that if this approach is just as effective as a radical procedure, the less mutilating treatment should be preferred.

Although the beliefs of the "intermediate" (i.e. radical-conservative) group about treatment effectiveness were similar to those of the "conservative group," radical surgery was still their preferred treatment for a 60 year old patient. While we cannot rule out that this was due to some anticipated contraindication for limited surgery in the older patient, their lack of consideration for the patient's right to share in the decision-making appears a more convincing explanation of their different behavior. When facing the same scientific uncertainty less "paternalistic" doctors (i.e. those attaching greater importance to patients' opinions) appear to be influenced by patient-centered outcomes (i.e. cosmetic) more than those who think they know what is in their patients best interest, thus relying more on physician-centered end-points (i.e. disease free-survival, total survival).

The original sample was drawn from among physicians working at a group of general hospitals participating in a program of quality of care evaluation.[6] Even if for some reason participating hospitals were not fully representative of all Italian physicians, this does not affect the internal validity of our findings. Furthermore, our findings favorably compare with other surveys on specialists[14] and non-specialists[10,17,18] in different countries. Studies from the UK,[18] USA,[10] and Canada[14] all consistently showed that surgeons, and to a limited extent also internists not specialized in oncology, are still more often in favor of radical procedures.

Data on actual practice would be stronger evidence of treatment preferences, but they are seldom available. Given that our study was done in a group of hospitals where a monitoring program on care given to breast cancer patients was going on,[6] it may be interesting to look at some comparisons between the two sources of information. Consistent with the key role of surgeons' opinions in the decision about surgery, we found—within a group of more than 1,000 cases of newly diagnosed patients in 1984–85[6]—that limited surgery was offered only to 25 percent of eligible patients. Also, data on actual practice confirmed the age-dependent orientation of doctors in that the more conservative operation was given to 34 percent of women younger than 50 years and compared to 21 percent among older patients.[6]

The public health implications of our study depend on the path of therapeutic decisions, which in turn depend on health care organization in different countries. In Italy, where cancer care is still seldom interdisciplinary, especially in community hospitals, it is worrisome that as many as 40 percent of surgeons—i.e. the specialists who decide about surgery—still favor radical surgery for an older patient and 11 percent even for a younger patient. This should not be seen as totally surprising since at the time this survey was carried out official recommendations of the Italian Breast Cancer Task Force were still in a transition period. They left open the choice of the most appropriate treatment indicating as acceptable both limited surgery and a more radical procedure (i.e. the Patey type of "modified" radical mastectomy).

Where cancer care is multidisciplinary (like in the US or Canada), it is likely that the more modern opinion held by other specialists is already forcing surgeons to change opinion and consequently practice. Less easy to predict is the extent to which changes in doctors' perception of patients' rights in treatment decision will affect prevailing practice in the near future. Considerations of this sort should be kept in mind when comparing results of patterns of care studies and physicians' surveys. ☐

Maternal Feeding Behavior and Child Acceptance of Food during Diarrhea, Convalescence, and Health in the Central Sierra of Peru

Margaret E. Bentley, PhD, Rebecca Y. Stallings, MHS, Mary Fukumoto, PhD, and John A. Elder, PhD

ABSTRACT

Feeding patterns by mothers and child acceptance of food were measured in a Peruvian village to determine changes on days when children had diarrhea as compared to days of convalescence and health. Morbidity surveillance identified 40 children, aged 4–36 months, with diarrhea. Children were followed using twelve-hour in-home structured observations during two to four days each of diarrhea, convalescence, and health. Using scales of maternal encouragement to eat and child acceptance of food and cumulative logistic regression analyses, maternal encouragement to eat decreased significantly during convalescence compared to diarrheal days (OR: 0.54, 90% CI: 0.35, 0.82) and health compared to diarrhea (OR: 0.65, 90% CI: 0.46, 0.93). In contrast, child acceptance of food increased during health compared to diarrhea (OR: 1.55, 90% CI: 1.02, 2.35). Results illustrate the importance of carefully examining the behavioral aspects of nutritional intake. Decreases in intake during diarrhea are due to anorexia and not withdrawal of food by mothers. In response to reductions in child appetite during illness, mothers are more likely to encourage children to eat, while they tend to become more passive feeders after the diarrhea has stopped. Program efforts should focus on messages to feed children more actively especially after diarrhea episodes, when appetite levels increase. (*Am J Public Health* 1991; 81:43–47)

Introduction

Worldwide studies of infant and child nutrition have demonstrated that poor infant feeding and weaning practices along with frequent infections, in particular diarrheal diseases, are important determinants of growth faltering and malnutrition in the developing world.[1–3] However, the primary focus of diarrheal disease control (CDD) programs has been on improved case management through the promotion of oral rehydration therapy, while dietary management has been relatively neglected. Where program messages do exist, they are generally quite vague—such as "continue feeding during diarrhea"—and therefore may be difficult for mothers and other caretakers to implement.[4]

The development of specific recommendations for feeding practices requires information about existing infant feeding practices during illness. In the absence of data, the public health community has often assumed that mothers in nearly all cultures withhold food from their children during diarrhea episodes.[5–8] This implies that modification of this ill-advised presumed behavior will reduce the negative nutritional effects of diarrhea. Such a perspective ignores the possibility that mothers may already be feeding their children during diarrhea, and that diarrhea-associated anorexia may be the major determinant of reduced dietary intakes.[9–10]

This study focused on the behavioral factors related to feeding during diarrhea, and assessed the relationship of illness to appetite in young children. In particular, we quantified the degree of effort caretakers applied to encourage children to eat and the acceptance of food by children during diarrhea episodes, the immediate postconvalescent period, and subsequent, symptom-free days of "health."

Methods

Data Collection

The study was conducted in a rural Andean village in the Callejon de Huaylas, Peru as part of the Dietary Management of Diarrhea program, funded by the United States Agency for International Development, Office of Nutrition. It was implemented in Peru by the Institute of Nutrition Research and the Federal and State Ministries of Health in collaboration with Johns Hopkins University. The project has been described in greater detail elsewhere.[11–12]

Morbidity surveillance in the study area identified children with diarrhea by visiting each household at 48-hour intervals. A total of 118 children, between the ages of 4–36 months, were under surveillance for 12 months. Diarrhea was defined as four or more liquid or semi-liquid stools/day, convalescence as 0–1 liquid or semi-liquid stools/day immediately after at least two days of diarrhea, and healthy observation days as an absence of any illness symptoms. This latter requirement was quite problematic, since children in this setting were frequently ill with some sort of infection.

TABLE 1—Mean Energy (Kcal/kg/day) and Protein (g/kg/day) Intake by Stage of Illness among Breastfed Children 4–36 Months of Age

Intake	Stage of Illness		
	Diarrhea	Convalescence	Symptom-Free
	n = 36	n = 36	n = 36
Kcal/kg/day	76*	85	86*
g/kg/day	1.3†	1.5	1.6

*Difference = 10 kcal/kg/day (p = 0.052)
†Difference = 0.3 g prot/kg/day (p = 0.009)
SOURCE: Esrey *et al*, FASEB 1988

Twelve-hour in-home structured observations of maternal and child feeding behavior were completed, during two to four days each of diarrhea, convalescence, and health. Forty children (drawn from the population under surveillance) were studied for the present study. Children were eligible for this study if, on the day of morbidity surveillance they met the criteria for diarrhea, if the episode was no more than one or two days old, if the children were not exclusively breastfed, and if a data collector was available to begin a set of 12-hour observations. Children were selected for across a full calendar year.

Weighed dietary intakes of the same children, reported in detail elsewhere,[13] demonstrate that there is a decrease in dietary intakes during diarrhea (Table 1). What remains to be explained is why these reductions occur.

A data sheet was developed to code observations of maternal feeding behaviors and child acceptance of food during each meal. A total of 787 meals were recorded for the 40 children. For 75 percent of the meals, mothers were the feeders, so we refer to "maternal feeding behavior" in our discussion. Neither the identity of the caretaker nor that of the observer was found to be significantly associated with either the mother's or child's behavior (data available from authors on request).

Behavioral observations were made at the level of the food or drink, for a total of 951 observations. Feeding observations of commercial oral rehydration solution (ORS) and non-caloric teas have been excluded. If a child consumed potatoes and soup during the same meal, the data collector would code child acceptance of food behaviors separately for each food. This was done because field testing showed that behaviors varied within a single meal episode, depending on the food offered. In addition, we wanted to assess whether children preferred or rejected specific types of food, either during illness, recovery, or health.

Data collectors were aware only that the purpose of the research was to measure diet and feeding behavior during illness, along with other household treatment behaviors. To check whether the invasive nature of the study methodology (that placed data collectors in homes for repeated 12-hour observations) may have influenced maternal feeding behavior, a series of three-hour feeding observations without weighing either food or children before and after breastfeeding were completed for 30 children. There were no significant differences in the frequency or duration of breastfeeding between the three-hour and 12-hour observations (data available from author on request).

Scale Construction

The data sheet contained five items measuring maternal feeding behavior and four items measuring child acceptance of food. Because these items had a logical order (i.e. mothers would not physically force children to eat if they had not already encouraged and pressured them verbally to eat), Guttman scaling techniques were used for scale construction.[14–15] The coefficients of reproducibility were quite high, .98 for Maternal Encouragement to Eat and .97 for Child Acceptance of Food, indicating that the observed response patterns fit closely the response patterns predicted by the Guttman analysis. After testing, three items remained in each scale.

For the Maternal Feeding Behavior scale the final items were: 'Verbally Encourage'→ 'Verbally Pressure'→ 'Physically force.' For the Child Acceptance of Food scale the items were: 'Rejects Food'→ 'Appetite Level'→ 'Asks for Food.' These two scales were then used as the dependent variables in the statistical analyses.

The Child Acceptance of Food scale was validated against actual intakes by comparing the mean scale for the day to the number of kilocalories from non-breastmilk for the day. Because the scale is ordinal rather than interval, Spearman's rho formula was used to calculate the correlation. The final Spearman correlation coefficient was .47, which shows a strong relationship between the scale and actual intakes.

There is no obvious means of validating the Maternal Encouragement to Eat scale against actual intakes. Increased encouragement to eat is a response to decreased appetite. The lower the appetite, the more encouragement children receive. Since maternal encouragement may or may not be successful, it is not clear that actual intakes should be associated with encouragement.

Cumulative Logistic Regression

To preserve the ordered categorical nature of the scales, cumulative logit procedures were used[16] and separate logistic regressions were performed for each cut-point (i.e. each ascending value on the scale). Because our early models indicated that the magnitude and direction of the beta estimates for various factors were not consistent across these cut-points, we were not able to make an assumption of "proportional odds," which would have allowed us to report only one set of final beta estimates. For the Maternal Feeding Behavior scale, only two cut-points were used because just 13 observations scored 3, which was too small a percentage of observations to compare with the 0–2 category.

The main hypothesis was that "stage of illness" affects both maternal and child feeding behavior, so this variable was entered into the model first. Then, because we knew that age should theoretically influence feeding behavior, we added age to the model as a categorical variable. The study design followed children prospectively through diarrhea, convalescence, and health, as they were aging. Children 4–5 months old were omitted from these analyses because they were few in number and inconsistent in preliminary analyses. Even with age in the model, "stage of illness" was significantly associated with feeding behavior and child acceptance of food.

Two different techniques were used to test for possible confounding factors, one following Kleinbaum, *et al*,[17] and one following Greenland.[18] Both were modified to allow the examination of polychotomous dependent and independent variables. On the Maternal Feeding Behavior

scale, variables were retained in the model if they were found to be confounders at either cut-point, while on the Child Acceptance of Food scale, variables were retained if they were found to be confounders at two of the three cut-points. Variables tested include, among others, type and consistency of food, caloric density of the food, kilocalories eaten at last meal, time since last meal, amount of breastmilk consumed during the observation period, the number of breastfeeding episodes, time of day, number of meals during the day, sex of child, identity of caretaker, and number of foods at a meal.

The variable fever (measured with a fever strip and later dichotomized) was deleted from the final analyses because, although highly significant in the preliminary analysis, the number of observations when fever was present (n = 17) was too small for multivariate analyses. However, a simple odds ratio of fever with appetite scores at cut-point 2 (corrected for intra-child correlation) shows that fever is much more likely to be associated with lower appetite (odds ratio = 0.06, 90% confidence interval: 0.01 to 0.46).

The final models were developed by adding to the model of stage of illness and age those variables that proved to be confounders. In addition, food consistency was added to both models since it was found to be closely related to both child appetite and maternal encouragement. Final variance estimates were corrected for the presence of intra-child correlation due to the longitudinal nature of the study design.[19]

Results

In the interest of brevity, the final models presented are those with cut-points closest to the median for both scales (Tables 2 and 3). However, when results for other cut-points differ significantly for the variables of primary interest, these are discussed.

For the Maternal Feeding Behavior scale (Table 2), when controlling for age and the other factors shown, the scores were significantly lower during convalescence and health compared to diarrhea (for the second cut-point, i.e., 0–1 vs 2–3, scores were not significantly lower for convalescence). In other words, mothers were more likely to encourage their children to eat during diarrhea episodes, compared to the other two intervals. In addition, mothers gave more encouragement when their children were eating liquid or semi-solid foods.

For the Child Acceptance of Food model (Table 3), when controlling for age and the other factors shown, children had lower food acceptance scores during diarrhea compared to health. For this cut-point, food acceptance scores were not significantly higher during convalescence, compared to diarrhea, but they were significantly higher in the model for the third cut-point (i.e., 02 vs 3).

Acceptance of food scores were higher when children were presented liquid or semi-liquid foods, compared to solids, regardless of stage of health. Twelve-hour breast milk intake was negatively associated with appetite on the child scale, indicating that higher levels of breast milk intake reduced appetite for non-breast milk foods. Breast milk consumption was measured by weighing the children immediately before and after breastfeeding.

Interestingly, in the preliminary screening, Kcals from breast milk consumed between meals was not signifi-

Goodman and Kruskal's Gamma = −.23851

cantly associated with the child's food acceptance at the subsequent meal, although the coefficients for this factor were negative, as was the case for 12-hour breast milk intake. We interpret this to mean that breastfeeding is associated with an overall reduction of child appetite for other foods, which cannot be adequately assessed at a meal level. This relationship did not appear to be confounded by time, as time since last breastfeeding was not found to be significantly associated with child's food acceptance.

Another function included in the screening, namely Kcal from either breast milk or non-breast milk consumed during the last feeding episode, was positively associated with child appetite at the current meal when comparing a high level of consumption (≥64 Kcal) to a low level (≤33.4 Kcal). However, the relationship was negatively associated when comparing an intermediate level (between 33.4 and 64 Kcal) to a low level. This same inconsistency was observed for the first cut-point, but for the third cut-point, both the intermediate and high levels were positively associated with child appetite. Because the positive association is consistent with the preliminary analyses, we expect that this is the correct direction.

A cross-tabulation of the scores on the Maternal Encouragement to Eat Scale and those on the Child Acceptance of Food Scale (Table 4) shows a clear negative relationship between the two scales, suggesting that mothers were increasing their efforts to feed their child as the child's appetite decreased. This relationship would have appeared stronger if the effect of food type was removed from both scales because the logistic analysis showed that both child acceptance and maternal encouragement increased when liquid and semi-solid foods were involved. The table also shows that these mothers were generally passive feeders, 64 percent of the time giving no encouragement to eat. These data corroborate the same finding in our early ethnographic work on this population. However, at the lowest level of child acceptance of food, over 70 percent of the time, mothers gave some encouragement.

Discussion

The results from this study demonstrate that these Peruvian mothers, normally quite passive child feeders, were more likely to encourage their children to eat during diarrhea episodes compared to both convalescence and health. Children experiencing diarrhea did appear to have observable reductions in appetite, and more often rejected food. These results corroborate our ethnographic data. Mothers frequently voiced concern that their children were "weak" and had reduced appetites during diarrhea.[11]

The more total kilocalories consumed by the child during the previous meal or breastfeeding, the better the appetite at the current meal. At first, this seemed counter-intuitive, but Esrey, *et al*,[13] found that these children averaged only 71 percent to 91 percent of recommended energy intakes, so if the children were not suffering from diarrhea or fever-induced anorexia, they would probably be willing to eat whenever food was offered. If this was the case, a child's appetite at any given meal would reflect the general level of health for the day rather than the amount consumed at the previous meal/breastfeeding, which was borne out by the positive relationship between appetite at the current meal and kilocalories consumed at the previous meal/breastfeeding. Again, this relationship did not seem to be confounded by time since last meal/breastfeeding, which was tested and was not significant.

What is the public health significance of these data? First, it is clear that in this setting mothers are not withholding food from their children when they experience diarrhea. Where this issue has been closely studied in other sites, similar results have been found. For example, in Nigeria, where we have used the same methodology as in this Peruvian site, mothers appear to force-feed their children more often when they have diarrhea, possibly as a response to their children's refusal to eat.[20] In India, some mothers shift the diet during diarrhea toward foods that they perceive as "helpful" and away from foods perceived as "harmful."[21] In each of these three sites, mothers' concern about appetite loss during diarrhea was high.[11,20-22] We hope that these data will replace the anecdotal information and survey data that reports that mothers "starve" their children during diarrhea episodes.

The role of anorexia during diarrhea appears to be an important factor in reductions of dietary intake during illness. We are not aware of other studies that have attempted to measure the degree of appetite of children in a field setting, although one clinic-based study suggested that anorexia was an important mechanism for reduced dietary intake during diarrhea.[23] Although it is expected that children's appetites should rise during the convalescent phase, in the present study this was observed only when logistic regressions were done that split children with high appetites into a separate group. In this case, child acceptance of food did rise during convalescence, suggesting that program messages should communicate to mothers the need to feed their children more during the recovery period. The data here show that mothers discontinued their more active encouragement to eat when diarrhea stopped, thereby missing an opportunity for their children to consume important "catch-up" nutrients. Program messages, therefore, should focus on a child's increase in appetite during the convalescent period, and encourage mothers to actively feed their children both during *and* after diarrhea. In addition, specific recommendations on foods appropriate during diarrhea and convalescence could be made and less emphasis placed on vague feeding messages. These messages should be based on cultural beliefs regarding appropriate foods to offer during diarrhea.[12]

We have shown a clear link between the presence of fever and the rejection of food by children. The effect of fever on appetite is worrisome because of the number of infections where fever is commonly present, such as upper respiratory infections and malaria. Lopez de Romaña, *et al*,[24] found fever present in children during 13.7 percent of all illness days, and Brown, *et al*,[25] reported an approximate 30 percent reduction in dietary intake among weanlings whose mothers reported the presence of fever, although Martorell, *et al*,[26] found no link between fever and growth rates. Clearly, more work is required to investigate the effect of fever on dietary intake and growth, and whether the administration of acetaminophen improves the acceptance of food by ill children (Gove, personal communication).

In conclusion, this study illustrates the importance of examining the behavioral aspects of nutritional intake. Simply measuring changes in caloric intake does not provide an explanation as to why the changes have occurred, so interventions may be based on faulty assumptions of behavior. In this case, mothers do not, as commonly assumed, withhold food from children with diarrhea. On the contrary, they actually increase their efforts to feed their children, as a response to the child's decreased acceptance of food. ☐

Acknowledgments

This work was supported primarily by the Office of Nutrition, Agency for International Development, Cooperative Agreement No. DAN-1010-A-5119-00, Dietary Management of Diarrhea (DMD) Project.

The authors would like to thank Dr. Kenneth Brown for his continued support, for his careful review of several drafts of the manuscript, and for data analysis suggestions. Dr. Gretel Pelto contributed to the early development of the structured observation instrument and reviewed an early draft of the paper. Dr. Robert Black also provided helpful suggestions of an early draft.

The Epidemiology of Licit and Illicit Substance Use among High School Students in Greece

Anna Kokkevi, PhD, and Costas Stefanis, MD

ABSTRACT

Findings on self-reported adolescent licit and illicit substance use are presented based on a nationwide 1984 probability sample of 11,058 Greek adolescent students ages 14–18 years old. Regular smoking and use of alcohol in the 30 days prior to the survey were reported by 22.3 percent and 82.8 percent, respectively. Nearly one-third of the students (30.3 percent) reported lifetime use of psychotropic drugs without prescription, without ever having used any illicit drug. Illicit drug use is less common in Greece than in other European and North American countries with a lifetime prevalence rate of 6 percent. Regular use of tobacco, alcohol, and illicit drugs was more common in males, while unprescribed use of licit psychotropic drugs prevailed in females. Regular smoking, drinking, and illicit drug use were associated with urbanization but not socioeconomic status. Between 1984 and 1988 in an Athenian subsample of schools there was a 20 percent increase in illicit drug use among males. Use of psychotropic drugs without prescription decreased much more than use of tobacco and alcohol. *(Am J Public Health* 1991; 81:48–52)

Introduction

In Greece, police reports and data from other sources indicate that use of illicit drugs was spreading in the late 1970s to young persons of all socioeconomic classes. Front-page newspaper articles alarmed the public and campaigns against drugs were initiated by lay groups.

This situation led the authorities to acknowledge the need for assessing the situation accurately. The Department of Psychiatry of Athens University was assigned the task of studying the extent of the drug problem in Greece and submitting proposals for appropriate preventive action.

The present paper presents an overview of illicit substance use among adolescent students in Greece, as well as related aspects such as smoking, alcohol drinking, and the use of licit psychotropic drugs without medical prescription.

Trends in licit and illicit substance use within the four years (1984–88) are also presented for Athenian high school students.

Methods

Nationwide Study

The sample is a nationwide multistage stratified probability sample. Urban areas were divided into three strata (Athens, Salonika, and all other urban areas); a fourth stratum consisted of all semi-urban and rural areas. Stage 1 of the sampling procedure involved the selection of urban, semi-urban, and rural locations, stage 2 the selection of high schools, and stage 3 the selection of classrooms within each high school. The allocation of the sample among the strata was proportional to the size of their student populations. The selection of sampling units in the first and second stages was proportional to their size. In each selected school, one class of about 30 students was selected with equal probability from each grade, and all students in the selected classes comprised the final sample.

The total sample consisted of 11,058 students ages 14–18 years attending the last four grades of high school. The secondary school system (high school) in Greece consists of six years; the first three years (Gymnasium) are compulsory and the second (Lyceum, either general or technical-vocational education) non-compulsory. Approximately 80 percent of Gymnasium students continue their studies in the Lyceum. The majority of schools are run by the state; only 6 percent are private fee-paying. The age of students in the Gymnasium is 12–14 years and in the Lyceum 15–18 years, with negligible deviations from this range. All 96 selected schools, representing all types of high schools, participated in the survey.

Data collection took place from March to May 1984. Students answered an anonymous questionnaire administered in their classrooms during two normal class sessions. The questionnaire consisted of structured pre-coded items covering a wide range of areas in addition to the use of licit and illicit substances: sociodemographic, school-related, physical and psychosocial health, life styles, future goals, personality and attitudes. ther's occupation and educational level as reported by the student were used in combination to assign students to three socioeconomic classes. This classification was validated by additional indices such as mother's educational level, housing, and estimated family income.

The average rate of absentees on the day of the survey was 6.1 percent. The participation rate of students present was 100 percent.

Reliability and validity of the responses concerning drug use were checked in a pilot study of 656 students conducted four months prior to the main study within the same school year. Students answered the questionnaire twice, with a 20-day interval, and questionnaires were matched by numbered stickers distributed at the first administration of the questionnaire.

Test-retest reliability coefficients were measured on 560 cases (85.4 percent of the total sample) for whom matching of the questionnaires was possible. Pearson's correlation coefficient for responses in seven categories ranged as follows: between .80 and 1.00 for tobacco smoking, drunkenness and lifetime and 12 month use of cannabis, cocaine, hallucinogens, and for 12-month use of heroin and opiates other than heroin; between .60 and .79 for lifetime and 12-month use of alcohol, stimulants, tranquilizers, hypnotics and for lifetime use of heroin and of opiates other than heroin, and .46 for lifetime use of heroin. Kappa coefficients[1] ranged as follows: between .71 and .89 for tobacco use and for lifetime and 12-month use of cannabis; between .41 and .50 for lifetime alcohol use, drunkenness, lifetime and 12-month use of hypnotics, for lifetime use of cocaine and opiates other than heroin and for 12-month use of tranquilizers; between .28 and .39 for 12-month alcohol use, lifetime and 12-month use of amphetamines, and lifetime use of heroin and tranquilizers. Reliability coefficients were significant at the .0001 level for 19 out of 20 usage variables examined and at .001 for the remaining one. No differences in reliability coefficients were observed between questions on drug use and other topics.

Validity was checked empirically by internal and external criteria:

- Rates of substance use and abuse in schools a priori known to have high rates of students with behavior problems and drug taking were compared with the rates reported in the remaining schools. Rates of reported experience with licit and illicit drugs proved to be substantially higher in the former schools for tobacco smoking, frequency of marijuana use in lifetime, last 12 months and 30 days, any use of heroin in the last 12 months and 30 days, any lifetime use of hallucinogens, opiates other than heroin, and lifetime and last 12 months' use of cocaine.
- 1.5 percent of the returned questionnaires were excluded from further analysis at the initial phase of checking because of major inconsistencies or unanswered parts of the questionnaires. In the retained questionnaires, internal consistency of answers was found to be very high, ranging from 85.5–100 percent.
- Urine was collected for the purpose of laboratory checking of general health status and substance use from 384 students in the four Athenian schools which participated in the pilot study. Students were informed of the general purpose of urine collection, but no specific mention was made of the substance tracing tests. Since anonymity was safeguarded, this procedure was in accordance with the ethical rules for investigations in Greece at the time. Urine samples were matched to questionnaires by the anonymous method of numbered stickers used in the test-retest procedure. Biochemical analysis for the detection of opiates, cocaine, and cannabis was performed by radioimmunoassay in the Instituto Superiori di Sanita (Rome). Results were positive for five of the 360 students for whom matching to questionnaires was possible: four were positive for cannabis and one for opiates. These five students had all responded positively to the pertinent questions but a further nine students (total rate 3.9 percent) reported use in the questionnaire without testing positive. Since reported use in the questionnaire covered the last 30 days while the bioassay techniques employed ensured detectability for only a few days following intake, some discrepancy in rates might be expected.

Study of Trends in an Athenian Sample

The sample in the 1988 survey consisted of classes from a randomly selected sub-sample of 18 schools from the 38 Athens area schools that had been included in the nationwide study of 1984. A total of 1,961 students participated in the survey. The average absentee rate on the day of survey was 5 percent.

A condensed version of the original questionnaire was used, covering only four out of eight categories of licit psychotropic drugs (tranquilizers, hypnotics, codeine, amphetamines) and three out of five illicit drugs (cannabis, heroin, cocaine). The same procedures were followed as in 1984 including test-retest reliability checks (135 matched pairs of questionnaires from 180 students over an interval of three weeks) and comparisons of rates of use in high-risk schools against the rest. Reliability and validity results were similar to those obtained in 1984.

Results

Nationwide Study

Over 70 percent of students reported having experimented at least once with tobacco smoking and 22 percent claimed regular smoking in the past month (Table 1). Regular smoking was highly correlated with sex and age, with more than one-third of the population smoking regularly in the older age group. The prevalence was much higher in the technical-vocational schools (41.9 percent vs 18.4 percent in public and 16.1 percent in private), in urban areas (23.7 percent vs 15.1 percent in semi-urban and rural areas), and lower in the higher socioeconomic level (19.4 percent vs 21.7 percent in the lower and 23.0 percent in the middle level).

The prevalence of alcohol use was 94.8 percent for past year and 82.4 percent for past month; 15.4 percent of students reported frequent alcohol use (10 or more times) in the past month. Rates of frequent alcohol use were twice as high in males as in females and nearly twice as high in the oldest as in the youngest age group (Table 1). Higher rates of frequent alcohol use were reported in private and technical-vocational in comparison to public schools (20.5 percent, 22.1 percent and 13.5 percent, respectively). Residence and socioeconomic level were not important determinants of the frequency of alcohol use. Heavy alcohol use (five or more drinks on one occasion) within the last 30 days was reported by 36.9 percent of students (44.4 percent male, 29.4 percent female) and increased from 32.2 percent in the 13–14 age group to 44.6 percent at 17–18 years.

Use of illicit drugs at any time was reported by 6 percent of students, with a ratio of two to one between boys and girls (Table 2). Approximately half of the users reported use more than twice.

The lifetime use of prescription requiring licit psychotropic drugs, without a doctor's order, was much higher than the use of illicit drugs, with a sex ratio of three girls to two boys. Nearly one-third (30.3 percent) of the student population reported that they had used unprescribed

Total rate	(10.812)	1.7	6.3	92.0
Sex				
Male	(5.396)	2.3	5.5	92.0
Female	(5.416)	1.2	7.1	91.7

*Students were assigned according to their reported use of drugs to two mutually exclusive categories: (a) "Pills"—use *without* doctor's orders of licit psychotropic drugs requiring prescription (amphetamines, anticholinergics, tranquilizers, hypnotics, barbiturates, antidepressants, at least once and analgesics or codeine-containing syrups more than five times) *but no use of illicit drugs;* and (b) use of illicit drugs (cannabis, hallucinogens, cocaine, opiates other than heroin, heroin). In the last category students might have also used licit psychotropic drugs without doctor's orders.

pain relievers or codeine-containing syrups more than five times or another licit psychotropic drug at least once, but had never used any illicit drug. If users of illicit drugs are included, 34.7 percent had used a licit psychotropic drug without a doctor's orders.

The frequency of use of unprescribed licit drugs and illicit drugs is shown in Table 3. These very high rates of unprescribed licit drugs might to some extent be due to the possibility that the students, despite instructions, had included in these categories over-the-counter drugs for pain and cough relief, not requiring prescription.

Use of both licit and illicit substances increased significantly with age. High rates of illicit drug use were observed in males of the older age group (14.5 percent) and high rates of licit drug use in females of the older age group (40.6 percent). Illicit drugs were used in higher rates in technical-vocational schools (9.9 percent) compared to private (6 percent) and public (5 percent) schools.

The rate of illicit drug use was related to city size, ranging from 6.4 percent in Athens to 4.4 percent in semi-urban and rural regions. Rates of illicit use increased with socioeconomic level, although differences were less marked. The only demographic variables influencing use of licit drugs were sex and age.

Licit and illicit substance use was found to be highly correlated: 15.5 percent of regular tobacco smokers had used illicit drugs compared to 2.5 percent of the rest of the population; 10.5 percent compared to 3 percent had used three or more types of licit psychotropic drugs without doctor's prescription. Among heavy drinkers, 24 percent had used illicit drugs, compared to 2.1 percent of the rest of the population; 17.4 percent compared to 3.4 percent had used three or more types of licit psychotropic drugs without doctor's prescription. Of those who had used three or more types of psychotropic drugs without prescription, 77.8 percent had also used illicit drugs, compared to 3.9 percent of the rest of the population. Moreover, 69 percent of those who had used illicit drugs other than heroin and 82.4 percent of those who had used heroin reported use of licit psychotropic drugs without a doctor's prescription ("pills").

Trends in Licit and Illicit Substance Use in the Athenian Sample

Comparisons of rates of substance use are based on the 18 Athens schools which participated in both 1984 and 1988.

Age was defined differently in the two surveys (year of birth in 1984, age last birthday in 1988), but this should have had only a small effect on comparisons.

A decrease was found in regular tobacco smoking for boys and a lesser decrease for girls (Table 4). The decrease in regular smoking was most striking in the two younger age groups.

Alcohol consumption also decreased between 1984 and 1988 in both sexes. The decrease in alcohol use is mainly due to a reduction in the number of occasional users (those who had drunk less than 10 times in the last 30 days). The proportion of frequent users in the oldest age group actually increased slightly.

Lifetime prevalence of psychotropic substance use on doctor's orders showed a substantial decrease for codeine (from 45.6 percent to 22.5 percent), whereas no

[*] Students were assigned according to their reported use of drugs to two mutually exclusive categories: (a) "Pills"—use *without* doctor's orders of licit psychotropic drugs requiring prescription (amphetamines, tranquilizers, hypnotics, codeine-containing syrups) *but no use of illicit drugs;* and (b) use of illicit drugs (cannabis, heroin, cocaine). In the last category students might have also used licit psychotropic drugs without doctor's orders.

significant change was found for tranquilizers, hypnotics, and amphetamines.

Lifetime prevalence of licit psychotropic drug use without doctor's orders ("pills") was markedly reduced in 1988, to almost half of the rate observed in 1984. On the other hand, lifetime prevalence of use of any illicit drug showed an increase of 20 percent for boys (from 6.5 percent in 1984 to 8.1 percent in 1988), while current use (past month) rates of illicit drug use almost doubled in both sexes. More specifically, lifetime rates of use increased from 6.1 percent to 7.5 percent for cannabis, from 0.9 percent to 1.7 percent for heroin, and from 1.3 percent to 2.3 percent for cocaine.

Discussion

The nationwide survey of Greek high school students shows a rate of illicit drug use much lower than the rates of 10 to 23 percent reported during the first half of the 1980s in similar studies in other European countries[2–6,*] and the rates of over 40 percent in the United States and Canada.[7–9]

Conversely, the overall use of licit substances such as tobacco and alcohol is higher in Greece than in the USA, Canada and northern European countries.[7,8,2,6,*] However, regular drinking is lower than in France,[10] and heavy drinking even lower than in the USA and Canada.[7,8]

The use of licit psychotropic drugs without a doctor's orders is much more common among the Greek students than the use of illicit drugs. In comparison to the US, the unprescribed use of opiates is more frequent in Greece, the use of tranquilizers is at the same level, and amphetamine and barbiturate use is less common.[7] Similar differences for the last three substances are found between Greece and Canada.[8]

---

[*] Hibbel B: Trends in drinking and drug habits in Swedish youth. Paper presented at the 27th International Institute on the Prevention and Treatment of Alcoholism, Vienna, 1981.

The spread of licit and illicit substances among students in Greece is, as elsewhere, influenced by legal and societal factors. Greece is a producer of alcohol and tobacco and thus the use of these substances is widespread. The traditional pattern of alcohol use in Greece is cultural and recreational, with consumption during meals and festivities where drinking by younger members of the family is not generally discouraged. Although the availability of illicit drugs is rather high due to the fact that Greece is a pathway in the illicit trade between Asian countries and the West, the use of cannabis and other illicit drugs is considered as criminal behavior and subject to severe penalties. On the other hand strict regulations for prescribing and purchasing of psychotropics have been strongly implemented only recently. Access to psychotropic drugs was therefore rather easy at the time of the nationwide survey.

Trends in the last four years in the Athens area suggest a possible impact of policy and of social attitudes on the use of psychotropic medicines but little change in tobacco and alcohol use. Campaigns against unwarranted prescription of licit drugs and the unprescribed use of medicines, as well as the stricter implementation of laws regulating their provision, seem to have had a substantial effect on consumption of licit psychotropic drugs without prescription. The significant drop in rates of prescribed codeine use between 1984 and 1988 may also reflect increased awareness of medical professionals of the addictive aspects of the substance. Although there was some tendency toward the decline of regular tobacco and alcohol use among younger students and that of occasional alcohol use in all age groups, rates of more frequent use of alcohol were unchanged in the older age group. More frequent users may be more resistant to sociocultural pressure for change.

Greece does not seem to have escaped the first stage of the course of the epidemic of illicit drug use, before the leveling off or even the decrease of the phenomenon, as observed in other European and North American countries within the last decade. There has been a rapid expansion across barriers of age and social class although illicit drug use is still predominantly associated with males, as was also seen in a nationwide survey of the general population.[11] Along with the increased use of heroin and cannabis, the recent surge of cocaine use indicates that users in Greece are following closely the preferences and patterns of illicit drug use in western Europe and North America. ☐

Acknowledgments

This research was supported by grants from the Ministry of Youth and Sports. We would like to thank Dr. Lloyd Johnston, Institute for Social Research, University of Michigan, for offering his valuable expertise to the study and the UN office in Athens for the provided support. We deeply thank all the contributors to the study and especially Dr. D. Madianou, Dr. M. Madianos, Mrs. M. Terzidou and Mr. Ch. Belopoulos. Dr. U. Avico, Instituto Superiori di Sanita, Roma, is gratefully acknowledged for substance detection in the urine samples and Dr. John Vlahonikolis, PhD, Department of Biometrics, Oxford University, for the statistical reliability and validity analysis.

AIDS-Related Knowledge, Sexual Behavior, and Condom Use among Men and Women in Kinshasa, Zaire

Jane T. Bertrand, PhD, Bakutuvwidi Makani, MS, Susan E. Hassig, DrPH, Kinavwidi Lewu Niwembo, Balowa Djunghu, Mbadu Muanda, L2, and Chirwisa Chirhamolekwa, L2

ABSTRACT

This study was conducted in 1988 among a random sample of 6,625 men and women of reproductive age in all 24 administrative zones of Kinshasa, the capital city of Zaire, to determine existing levels of knowledge regarding AIDS (acquired immunodeficiency syndrome), sexual behavior, knowledge and use of condoms in marital and extramarital relations; perceived risk of AIDS, and attitudes toward testing for the human immunodeficiency virus (HIV). Awareness of AIDS is almost universal, and the vast majority know the four main modes of transmission. Almost half believed in transmission by mosquitoes and in a vaccine or cure for AIDS. The majority of male respondents knew of condoms, but negative attitudes toward condom use are widespread, and few respondents perceived them to play a central role in combatting AIDS. (*Am J Public Health* 1991; 81:53–58)

Acquired immunodeficiency syndrome (AIDS) constitutes a major public health problem in Zaire. It is estimated that 6–8 percent of the adult population of Kinshasa, the capital city of Zaire, are seropositive, based on serosurveys of selected populations.[1] Six percent of babies delivered in the two major hospitals in Kinshasa in 1987 were born to seropositive mothers.[2] In 1988, 50 percent of the admissions to the internal medicine ward of the major public hospital, Mama Yemo, were HIV (human immunodeficiency virus) seropositive.[3] It is estimated that 80–90 percent of AIDS in Kinshasa is transmitted through sexual contact.[1] Since homosexuality is rare in Kinshasa, heterosexual relations constitute the major means of AIDS transmission among this population.

Until a vaccine or cure is found, public information and education remain an important weapon against AIDS. Since 1987, AIDS messages have been broadcast frequently on radio and television. Luambo, a popular singer in Zaire, further publicized the dangers of AIDS through a widely diffused song.

The current study was conducted city-wide in 1988 among the adult population to measure awareness of AIDS, its modes of transmission and means of prevention; coital frequency and extramarital sexual relations; knowledge and use of condoms; perceived risk of getting AIDS; and attitudes toward HIV testing. This module on AIDS formed part of a larger survey on contraceptive prevalence in Kinshasa, conducted by the Projet des Services des Naissances Désirables, the national family planning services project.

Methods

The projected sample for this survey consisted of 1,500 men (ages 20–59 years) and 1,500 women (ages 15–49 years), randomly selected from the 24 administrative zones of Kinshasa. The age criterion differed by sex, in an effort to obtain the population at greatest risk of AIDS. Four zones were intentionally oversampled for other research purposes (a field study to test the impact of an AIDS prevention program, not reported herein), bringing the projected sample size to 2,500 per sex.

Two-staged sampling was involved: first, 72 of 251 *quartiers* (the largest administrative unit within an administrative zone) were randomly selected and subsequently mapped; second, *parcelles* (a compound containing one or more households) were systematically selected. Men and women were interviewed in alternate *parcelles*; thus, the male/female data constitute independent samples, not husbands and wives.

About the co-authors: Bakutuvwidi is Consultant, Centre d'Informations Techniques et de Recherches pour le Développement, Kinshasa, Zaire; Dr. Hassig is Research Assistant Professor, Biostatistics and Epidemiology, Tulane SPHTM, New Orleans; Kinavwidi is Statistician, Institut National de la Statistique, Kinshasa; Balowa is Head of Computer Services, Mbadu is Head of Operations Research, and Chirwisa is Director, all three with Projet des Services des Naissances Désirables (the Family Planning Services Project), Kinshasa. This paper, submitted to the Journal June 19, 1989, was revised and accepted for publication March 21, 1990.

TABLE 1—Sociodemographic Characteristics of the Study Population*

	Men N = 3140	Women N = 3485
Age (years)	%	%
15–19	—	23.0
20–24	23.5	23.2
25–29	36.2	20.0
30–34	12.8	14.6
35–39	9.8	10.2
40–44	9.6	5.6
45 and over	8.1	3.2
Mean age (years)	33.4	26.6
Highest educational level attained		
None or primary	19.1	36.4
Secondary	61.0	60.5
Beyond secondary	19.5	2.7
Marital status		
Married (1 wife)	53.1	44.1
Married (2+ wives)	4.3	8.3
Consensual union	2.0	9.5
Separated, divorced, or widowed	3.6	8.5
Single, never married	37.0	29.5
Household amenities		
Has electricity	33.6	35.3
Has running water in house	9.2	7.8
Has toilet inside house	11.5	8.6
Has a working radio	51.8	49.3
Has a car or truck	9.4	7.0

*The "N" given in this and all subsequent tables is based on the unweighted sample (i.e. actual number of people who answered the question); the percentages are based on the weighted sample.

Because the average number of eligible respondents per *parcelle* was higher than expected, the total number of respondents (6,625) exceeded the projected sample. In the tables below, the results have been weighted to adjust for oversampling. The n in each case is based on the unweighted sample (actual number of people who were asked the question), whereas the percentages are based on the weighted sample.

Data collection for this survey took place from January to September 1988. All interviewers underwent a 20-day training course on sampling and data collection procedures prior to the fieldwork. All interviews were conducted in Lingala, the local language, by an interviewer of the same sex, using a pretested, structured questionnaire. Each interview lasted an average of 30-40 minutes.

All questionnaires were verified for completeness and logical consistency; where necessary, interviewers were sent back to the field to verify or complete responses. SPSS/PC + and BMDP/PC were used for the analysis.

Results

The total sample included 3,140 men and 3,485 women (Table 1). Over half of all respondents had at least some level of secondary education; however, significantly more men (20 percent) than women (3 percent) had gone beyond secondary school. The majority of men (59 percent) and women (62 percent) were married or living in consensual union.

Knowledge of AIDS

Awareness of AIDS is almost universal in Kinshasa (99 percent of men and 96 percent of women). Details of specific AIDS knowledge items are presented in Table 2. Of note, only half the study population knew that mosquitoes do not transmit AIDS and only 70 percent had correct information regarding casual contact. Ninety-four percent of men and 88 percent of women believed that AIDS could be prevented through behavioral changes.

Thirty-six percent of men and 45 percent of women at the time of this survey believed that there was a vaccine against HIV. Moreover, 40 percent of men and 21 percent of women believed that a person with AIDS can be cured. An additional 5–12 percent were unsure regarding both of these points.

Seventeen percent of men and 31 percent of women knew someone with AIDS at the time of the interview. Half of all respondents knew at least one person who had died of AIDS.

All respondents who had heard of AIDS were asked whether they had seen or heard something about AIDS via different communication channels. More adults in Kinshasa have been reached via radio than any other medium: 96 percent of men and 83 percent of women. Almost identical percentages of each group reported having heard the Luambo song on AIDS. A slightly lower percentage (86 percent of men, 70 percent of women) had seen something about AIDS on television. The percentages who had seen brochures, newspaper articles, or posters on AIDS were lower, ranging from 38–60 percent for men and 22–34 percent for women.

The vast majority of respondents, 95 percent of men and 89 percent of women, wanted to learn more about AIDS.

Multivariate Predictors of Knowledge of AIDS

In a multiple regression of the summed knowledge score by demographic and descriptive variables, males and females both had similar results (Table 3). Higher knowledge scores in both groups were associated with higher socioeconomic status (SES), higher educational attainment, length of time and number of messages they had heard about AIDS, personally knowing someone who has AIDS or had died of AIDS, and professing to a non-Christian religion. Being raised in a rural environment was negatively associated with knowledge for women, but not for men. Being older was negatively associated with knowledge for men but not for women. (In both males and females, age was negatively correlated with level of education.) Despite the number of significantly associated variables, the adjusted r square for both the male and female models was only 0.18. Thus, it is apparent that the variability seen in the knowledge scores in this population cannot be truly defined by the available variables.

Sexual Behavior, Knowledge, and Use of Condoms in Marriage

The median age at first sex (among those who had initiated sexual relations) was 17 years for men and 16 years for women. One percent of men and 14 percent women had not had sex, while 9 percent men and 4 percent women did not respond to the question.

All married respondents (N = 4,008) were asked whether they had had sexual

TABLE 2—AIDS Knowledge Items and Perceived Risk of HIV Infection among Those Who Have Heard of AIDS (percent with correct response)

	Men N = 3099	Women N = 3351
The AIDS virus is transmitted by:		
• eating unclean food	82.6	76.6
• transfusion with infected blood*	96.8	92.7
• mosquitoes	50.5	55.3
• sexual relations with an infected person*	98.7	96.4
• living in the same house with AIDS patient	66.5	56.6
• injection with unsterile needle*	95.7	91.3
• wearing used clothing	71.0	63.7
• working beside an AIDS victim	71.3	62.4
• (infected) mother to fetus*	94.0	89.2
The following are symptoms of AIDS:		
• frequent vomiting	63.5	63.5
• prolonged diarrhea*	81.6	81.7
• heavy bleeding for women	63.3	63.9
• recurrent fever*	45.2	43.2
• extreme weight loss*	78.2	68.7
• loss of hearing	75.2	73.6
• pain in the joints	57.1	56.1
• general, prolonged fatigue*	43.4	28.8
Transmission beliefs:		
• person can be infected without knowing*	87.9	77.5
• person can be infected without feeling sick*	84.5	73.1
• person who feels healthy could transmit the AIDS virus to another person*	84.2	72.1
• person with multiple partners has more risk than person with one partner*	78.9	72.6
• it is advisable for a woman infected with AIDS virus to get pregnant	97.4	95.7
• person infected with the AIDS virus will eventually get the disease*	76.0	71.2
There is a vaccine againt AIDS	58.6	43.1
AIDS can be cured	52.0	68.0
AIDS can be prevented*	93.7	88.0
AIDS can be prevented by:		
• taking antibiotics before sex	81.5	65.4
• using condoms for extramarital sex*	70.1	41.6
• going to a traditional healer	90.3	79.1
• avoiding sex with multiple partners*	93.7	85.4
Perceived risk of contacting AIDS:		
• Very high	10.6	10.2
• Moderate	6.8	5.9
• Low	21.0	9.3
• None	46.8	62.9
• Don't know	13.8	11.3

The asterisks above indicate which items are correct as stated.

relations in the previous month; 66 percent of 1,885 men and 60 percent of 2,123 women reported having had relations during this period. Abstinence was associated with the postpartum period or having an absent partner. Among those married respondents who had had relations, the mean number of days of sex during the previous week was 1.3.

Over 90 percent of married and single men, 77 percent of married women, and 61 percent of single women had heard of condoms. Despite the high recognition level, relatively few of the respondents in this survey had ever used condoms, with 12 percent of married men reporting ever using them with their spouse.

Eight percent of married men and 7 percent of married women reported current condom use with their spouse, although less than 2 percent of either sex reportedly used them "always" or "most of the time." The predominant reason for using condoms with one's spouse was to prevent pregnancy; the second, to prevent sexually transmitted diseases (STDs) in general, and the third to prevent AIDS. Mention of pregnancy prevention was higher among married than single respondents (reporting on condom use with their current partner), whereas singles cited prevention of other STDs and AIDS more often than married respondents.

Extramarital Relations and Use of Condoms

Twenty-three percent of married men and 1 percent of married women reported having had an extramarital partner or partners in the past six months; 12 percent of men and 1 percent of women reported such relations in the four weeks preceding the interview. Of men having had extramarital activity in the past six months, half reported having only one such partner (Table 4). Among the relatively few women who admitted to extramarital sexual activity, almost all claimed that it was with a single partner.

Factors associated with extramarital activity in men included younger age (<35 years), moderately higher education and SES levels, increased belief in the existence of a vaccine against HIV, and residence in a major urban area since adolescence. Men acknowledging extramarital activity also had slightly more misconceptions regarding false modes of HIV transmission, had heard more messages regarding AIDS than those denying extramarital activity, were more likely to cite condoms as a prevention method for AIDS, to perceive themselves to be at "very high" or "high" risk of AIDS, and to have known someone who had died of AIDS.

In women, the factors linked with such activity were more difficult to define, given the small numbers of women who acknowledged the behavior, but a few basic factors were similar to the men: younger age and urban residence since adolescence were associated with extramarital activity.

While the numbers are admittedly small, condom use was higher with extramarital partners (24 percent among men, 12 percent among women) than with one's spouse. In addition, the frequency of use was more consistent with extramarital partners than with spouses; half of the male users did so "always" or "most of the time." Among unmarried men, 27 percent reported having used condoms with their current partner, with a frequency of use similar to married men in their extramarital relations.

Attitudes toward Condoms

Over 52 percent of all male respondents believed that condoms tear easily during sexual relations, that they can stay in the vagina after sex, and that they diminish sexual pleasure. An additional 12–28 percent had no opinion on these questions. Single men were slightly more favorable toward condoms than married men.

TABLE 3—Multiple Regression of Summed Knowledge Score by Demographic Variables*

	Male		Female	
	Coeff	SE of Coeff	Coeff	SE of Coeff
Socioeconomic status	0.4488	0.0706	0.3709	0.0798
Age	−0.0295	0.0116	−0.0025	0.0136
Non-Christian religion	−0.2165	0.1008	−0.4542	0.1157
Multiple partners or extramarital partners	−0.0503	0.0680	0.6069	0.5444
Time source heard of AIDS/HIV	0.3650	0.0608	0.2405	0.0636
Number of information channels	0.4384	0.1027	0.8820	0.1240
Know someone with/died of AIDS	0.5844	0.1859	0.6707	0.2181
Rural residence	0.0384	0.1062	−0.3273	0.1245
Level of education	0.7765	0.1284	1.0612	0.2135
Marital status	0.2859	0.2275	0.1092	0.2193
	Adjusted $R^2 = 0.18$		Adjusted $R^2 = 0.18$	

*The knowledge score is based on one point for each correct answer to the items listed in Table 2 (except for "perceived risk").

TABLE 4—Frequency of Extramarital Relations and Condom Use among Married Respondents Who Have Heard about AIDS

	Men N = 1885	Women N = 2123
Number of extramarital partners in past 6 months		
0	77.4	98.6
1	11.7	1.3
2	5.6	0.1
3	2.9	-
4 or more	2.3	-
Percentage reporting extramarital relations in past four weeks	12.1	1.2
Among those with extramarital partners in past 6 months	(N = 401)	(N = 22)
% who use condoms with extramarital partners	24.0	11.8
Among these condom users the frequency of use	(N = 90)	(N = 4) (N too small to report %)
Always	35.4	
Most of the time	14.5	
Sometimes	27.4	
Never	22.7	

Among women, 30–50 percent believed that condoms have the above-mentioned disadvantages. However, well over 30 percent of both married and single women answered "don't know" to these questions, which could reflect their ignorance of the method, lack of experience with condoms, or embarrassment over the questions. Married women were slightly more knowledgeable or favorable than single women (data not shown).

Factors associated with condom use and with relatively positive attitudes toward condoms for men were younger age (<35), having had extramarital activity or multiple partners in the last six months, and not having a steady partner. Men with positive attitudes toward condoms were more likely to have used condoms and to cite condoms as a means of HIV prevention. Neither SES, education, religion, nor urban residence showed any association with condom attitudes (data not shown).

Perceived Risk of Getting AIDS

Table 2 shows the distribution of perceived risk in the male and female study populations. What is most striking is that 47 percent of men and 63 percent of women believed that they were at no risk of getting AIDS. For men, factors associated with an increased perception of risk include younger age, higher education and SES levels, knowing someone who died of AIDS, having less accurate knowledge regarding false modes of HIV transmission, having heard more messages regarding AIDS, being either Catholic or Protestant, and having had multiple sexual partners or engaged in extramarital activity in the last six months.

An increased perceived risk in women was associated with higher education and SES levels, engaging in extramarital activity or having multiple sexual partners, having heard more messages regarding AIDS and knowing of AIDS for a longer period of time, receiving their AIDS information from informal sources such as friends and neighbors, and knowing someone who died of AIDS. Women with high perceived risk also had less knowledge regarding common means of AIDS prevention and were slightly more likely to recognize that there is no available vaccine. Surprisingly, women who had a stable or regular partner also perceived themselves to be at increased risk versus those women without such a partner. This may be a reflection of female awareness of or concern over male infidelity.

The association of perceived high risk with misconceptions regarding modes of AIDS transmission and means of prevention suggests that at least a part of this perception may not be based on fact. However, considerable denial regarding AIDS risks is also playing a role in this population. Although having multiple sexual partners is a well-recognized risk behavior for AIDS, 74 percent of men actually engaging in extramarital relationships perceive themselves to be at little or no risk of AIDS.

Attitudes toward Testing for the AIDS Virus

Thirty-nine percent of men and 16 percent of the women had heard of the term "seropositive"; two-thirds of those who claimed to know the word defined it correctly. The majority of respondents, 78 percent of men and 57 percent of women, reported that they would accept being tested for HIV. Over 90 percent of respondents would want to be informed if either they or their spouse or child were diagnosed with AIDS or HIV infection.

TABLE 5—Perceived Risk of AIDS and Correlates of High Perceived Risk

	Men N = 3099	Women N = 3351

Discussion

The results of this study provide the first available data on levels of knowledge and attitudes with regard to AIDS among a probabilistic sample of the adult population of Kinshasa. While awareness and knowledge may have increased since the study ended in September 1988, the results nonetheless constitute a useful basis for the planning and evaluation of future information-education-communication (IEC) activities for AIDS.

Awareness regarding transmission of HIV via sexual contact is very high, but misconceptions persist over transmission by casual contact and mosquitoes. The fact that only a relatively low percentage could identify symptoms of AIDS may be explained by the fact that health officials have not stressed these aspects in their educational messages.

The misconceptions among a significant portion of the population regarding a vaccine and cure for AIDS are reason for concern, since they may create a sense of false security. The belief regarding the vaccine may result from periodic news stories about vaccine research ongoing in Zaire. The belief that AIDS can be cured may also be attributable to the widespread publicity about a new drug "MM1," which was presented to the Zairian public in November 1987 as a treatment for AIDS. Two recent surveys in different populations have shown a drop over the past year in the percentage that believe in a vaccine and/or cure.[4,*]

Comparisons between the Kinshasa population and a May-June 1988 nationwide survey of the adult population in the United States[5] reveal that both populations were highly knowledgeable on modes of transmission and reported a high level of exposure to AIDS messages via the mass media; in Zaire the most far-reaching channel was radio, whereas in the US it was television.

However, the two populations differed markedly in several other respects: belief in a vaccine or cure for AIDS was far more common in Zaire, while belief that condoms were effective prevention measures was less common in Zaire. These differences also underscore the areas in which campaigns in Zaire will need to be more explicit.

This study is the first to provide data on two key variables related to HIV transmission—extramarital relations and condom use—from a large, probablistic sample of both men and women in Zaire. The responses to the questions on sexual behavior should be interpreted with some caution, however, as such items are highly sensitive.[6] Based upon anecdotal evidence from Kinshasa residents, it was initially believed that the current data underestimated both coital frequency (median number of days of sex per week: 1.3 for married respondents) and extra-marital relations (23 percent of married men and 1 percent of married women in the past six months).

However, our findings are similar to results obtained from a study of over 12,000 workers and their spouses in two businesses in Kinshasa.[7] Among, 4,487 married couples, the mean number of days during the past year in which the couples had sex was 84; this yields a mean of 1.6 days per week. Regarding extramarital sex, 29 percent of married men reported at least one extramarital partner in the past 12 months. This percentage is slightly higher than that found in our study but covers a 12-month rather than six-month period. The question of extramarital relations was posed to females at only the smaller of the two study sites and yielded a prevalence similar to ours (<2 percent).

By contrast, in a study of health personnel (ranging from doctors to traditional practitioners) from all regions of Zaire except Kinshasa, the percentage of men reporting a history of extramarital relations in the past was 58 percent in 1987, dropping to 43 percent in 1988; among women, these percentages were 29 percent in 1987, decreasing to 18 percent in 1988.[8] These percentages are substantially higher than those found for the Kinshasa population in general. Possible explanations for these differences could be that the time period for the activity was not clearly specified, the health workers had greater economic means with which to engage in such activities, or they felt more comfortable with the circumstances in which the information was obtained.

We believe that the data from the current study underestimate the extent of extramarital relations, especially among women. In a subsequent study of sexual behavior in Kinshasa based in part on focus groups, both male and female participants were asked whether married men and married women would be likely to answer truthfully to questions regarding extramarital relations on a survey. The general consensus was that it depended on the interviewer's skill at putting the respondent at ease. However, there was strong consensus that a married woman

---

[*] Bertrand J, Bakutuvwidi M, Balowa D, Kinavwidi N: Knowledge of AIDS, sexual behavior and condom use in ten sites in Zaire. American Public Health Association annual meeting, Chicago, October 1989.

could not risk revealing anything about extramarital affairs, lest this get back to her husband."**

The findings with regard to knowledge and use of condoms among married women concur with previous studies in Zaire.[9-11] In addition, the data from the current study confirm the widespread supposition that condoms are used much more frequently for extramarital sex than for relations with one's spouse. Despite the fact that relatively few men report having used condoms, the majority claim that they tear, stay inside the women's vagina, and decrease sexual pleasure. These negative attitudes must be based on conjecture rather than experience. Unsubstantiated rumors have apparently discouraged the use of condoms to such a degree that the Zairian public does not perceive their importance in the fight against AIDS. The percentage of married men and married women reporting current condom use yielded very similar results from two independent samples. This refutes the hypothesis that women tend to underreport condom use (at least for relations with one's spouse), an issue which has been raised in connection with female-only contraceptive prevalence surveys.

Regarding perceived risk, most of the individuals engaging in extramarital and multiple partner sexual activity did not acknowledge any perception of risk, even though the majority of these same people intellectually "know" that sexual activity with multiple partners provides an elevated risk of HIV exposure. In addition, many persons with high perceived risk believed in the possibility of mosquito-born and/or casual transmission. An unfounded perception of risk, such as this, may be counterproductive in the course of HIV infection and AIDS. If people persist in fearing casual contact with infected individuals, the subsequent ostracism of such persons will place an unmanageable burden upon limited governmental resources. It may also limit the population's response to efforts to promote behavioral change.

To conclude, the findings from this survey have several important implications for ongoing and future efforts to prevent the spread of AIDS in Kinshasa:

- Greater efforts are needed to combat the still prevalent misconceptions that AIDS can be transmitted by casual contact and by mosquitoes.
- IEC efforts should reinforce the idea that the two main means of protection from sexually transmitted HIV infection or AIDS are total mutual fidelity within monogamous couples and where that is not considered possible, use of condoms.
- Condom promotion should include messages directed at changing the negative attitudes toward condoms reflected in this study.
- Information campaigns should emphasize the fact that there is no effective vaccine against AIDS and that the disease is fatal.
- Education campaigns should be directed at teens as well as adults; by the age of 17, half of males and females have engaged in sexual relations. ☐

Acknowledgments

The authors wish to thank the following individuals for their participation in this effort; Mukoka Makolo, Chigangu Munyerenkana, Muhemeri Chirezi, Makunsa Ntimansiemi, Nzila Nzilambi, Ngoie Mbuya, Bradley Barker, Lois Bradshaw, and Carol Dabbs.

Support for this research was provided by: USAID, Office of Population, Washington, DC (cooperative agreement no. DPE-3030-A-4051-00); and by USAID/Zaire (contract no. 660-0094-0-C-00-8111-00).

The Course of the HIV Epidemic among Intravenous Drug Users in Amsterdam, The Netherlands

Harry J.A. van Haastrecht, MS, Johanna A.R. van den Hoek, MD, PhD, Christiane Bardoux, MD, Anne Leentvaar-Kuypers, MD, and Roel A. Coutinho, MD, PhD

ABSTRACT

To determine if behavioral changes in intravenous drug users in Amsterdam have retarded the HIV (human immunodeficiency virus) epidemic in this group in recent years, we report that: HIV-antibody seroprevalence in annual samples of injectors has been constant over the years 1986–89; HIV-antibody incidence in a cohort of injectors appears to have decreased from 1986 to 1987 and stabilized after that until 1989; acute hepatitis B incidence in all drug users in Amsterdam declined rapidly between 1985–89. It is concluded that changes in drug use behavior so far appear to have resulted in a stabilization of the epidemic among injectors, at a level with a still disturbingly high incidence rate of 5–6 per 100 person-years. (*Am J Public Health* 1991; 81:59–62)

Introduction

Intravenous drug use was the only risk factor in 75 (7 percent) of the 1,074 AIDS (acquired immunodeficiency syndrome) cases diagnosed and reported in The Netherlands by December 31, 1989. Forty-five of these cases were residents of Amsterdam (P. Bindels, personal communication). Although the absolute number of AIDS cases among intravenous drug users in this city of approximately 700,000 inhabitants is still relatively small, the rate of the recent increase is high: from one new case in 1985, three in 1986, eight in 1987, and 15 in 1988 to 18 new cases in 1989. In an effort to stop or slow down the spread of HIV among drug users, a number of national and local policies have been developed and applied. The informational programs directed to drug users, on the dangers of AIDS and on ways of preventing infection (since 1986), were supplemented by supplying condoms to addicted prostitutes. In 1984, a needle and syringe exchange program was implemented,[1,2] the original purpose of which was to prevent the spread of hepatitis B. All of these policies aim at voluntary behavioral change, by reducing risk behavior and thereby limiting the occurrence of new HIV infections. Evidence based on self-reporting suggests that behavioral change toward safer drug using practices did indeed occur in Amsterdam in recent years. A study previously published in this Journal,[3] showed that in a cohort of intravenous drug users a marked increase in making exclusive use of the Amsterdam needle and syringe exchange program occurred during the period December 1985 through July 1988 with a concurrent marked reduction in sharing used needles and syringes. Self-reported changes in behavior have their limitations and more objective measures of risk reduction are needed to corroborate these findings. The aim of this study therefore is to describe several of these more objective indicators for the development of the HIV epidemic among drug users in Amsterdam during the past few years.

Three indicators will be dealt with: 1) HIV seroprevalence among intravenous drug users at intake into a study from 1986 through 1989; 2) incidence of HIV infections in a cohort of intravenous drug users from 1986 through 1989; and 3) incidence of acute hepatitis B infection among drug users in the city of Amsterdam from 1983 through 1989. In drug users, hepatitis B virus (HBV), like HIV, is transmitted mainly through the sharing of needles and syringes. Acute hepatitis B infection was therefore chosen as a surrogate marker for HIV infection. In homosexual men, where both HBV and HIV also share the same main transmission mode (anogenital intercourse), a close correspondence between hepatitis and HIV incidence was shown.[4]

Methods

Study Participants

Participants were recruited at six methadone maintenance outposts and at a weekly sexually transmitted diseases

clinic for drug-using prostitutes. Both intravenous and non-intravenous drug users were invited to participate. After informed consent was obtained, a blood sample for HIV serology was taken and participants were interviewed using a standard questionnaire. Participants were asked to return for follow-up examinations every four months for repeat interviews and blood samples. There was no payment for their first visit; those who continued participation in the study were offered 25 Dutch guilders as an incentive for each follow-up visit. HIV antibody tests were performed using standard procedures described elsewhere.[5] The intake of participants started December 1985 and continues to the present.

Results reported here pertain to the period January 1986 to the end of 1989. Participants who reported at intake ever having used drugs intravenously were considered intravenous drug users (IVDUs) and were all included in the HIV-seroprevalence analysis. The HIV-incidence analysis was limited to those follow-up participants who had used drugs intravenously within the five years preceding intake or who (re-)started intravenous drug use in the course of follow-up. IVDUs with a positive HIV-antibody test result at entry were more inclined to take part in the follow-up than those who tested negative; 69 percent versus 57 percent, respectively, returned for at least one follow-up visit by March 1990. Risk factors for the presence of HIV-antibody that were more often present in those in follow-up than in others were: recently injecting, residing in Amsterdam for more than two years, and German nationality.

HIV-Seroprevalence and -Incidence

The development of the HIV-seroprevalence rate over time was examined by separating the intakes according to year of intake (1986–89). Since participants were self-selected, it is conceivable that IVDUs with different probabilities of being seropositive entered the study at different times. To control for such a selection bias, predetermined risk factors[5] that predict the probability of being seropositive and that were presumed not to reflect policy-induced behavior changes were multivariately controlled by logistic regression, using standard statistical software.[6] These risk factors were: date of first and date of last injection, nationality, length of stay in Amsterdam, and frequency of smoking of heroin in past six months. Annual incidence rates were calculated by determining the number of seroconversions per 100 person-years for those at risk. At risk were considered IVDUs who were HIV-antibody negative at entry, from their first visit until their last one or until seroconversion. Date of seroconversion was estimated as the midpoint of date of last seronegative visit and date of first seropositive visit.

Incidence of Acute Hepatitis B

All cases of acute hepatitis B in Amsterdam must be reported to the Municipal Health Service. On a routine basis, background data including drug use are collected in a personal interview by a public health nurse. This procedure remained unchanged throughout the study period. All records of acute hepatitis B cases from 1983 through 1989 were carefully screened by one of us (CB) for cases with a history of illicit drug use. Incidence was calculated by using estimates of the total number of hard drug users present per year as denominator; these estimates were calculated by the Municipal Health Service's drug department, based on a capture/recapture method quarterly[7] and have wide margins of uncertainty. We assumed there was a constant proportion of injectors among these drug users during the study period.

Results

HIV-Seroprevalence

A total of 622 subjects who had ever used drugs intravenously participated in the study between January 1986 and December 1989 (Table 1). In four consecutive years (1986–89), both the crude HIV seroprevalence rates and the adjusted rates (taking 1986 as year of reference) remained between 27.8 percent and 34.1 percent with no trend effect (Table 1).

HIV-Incidence

A total of 236 subjects who were seronegative at entry into the study and who reported intravenous drug use either within the five years preceding entry or in the course of follow-up, were analyzed to determine incidence. Twenty-seven seroconversions were recorded: five in 1986, six in 1987, eight in 1988, and eight in 1989.

The incidence rates per 100 person-years (95% confidence interval) were: 10.7 (1.3, 20.0) in 1986, 5.6 (1.1, 10.1) in 1987, 5.6 (1.7, 9.5) in 1988, and 5.5 (1.7, 9.4) in 1989 (Figure 1). The incidence rate difference between 1986 and 1987 was 5.0 (−5.3, 15.4).

Acute Hepatitis B Incidence

The incidence of acute hepatitis B (AHB) per 10,000 varied from a high of 48 in 1984, to a low of 8.6 in 1989 (Figure 2). Over the seven-year time span under study, there was a significant decline in AHB incidence (χ^2 for trend = 23.5, df = 1, $p = 10^{-6}$).

Discussion

These data suggest a decline in HIV-seroconversion from 1986 to 1987, followed by stabilization up to 1989. The confidence intervals, however, are broad, indicating that the early decline is not conclusive. In San Francisco, a similar decline was noticed in HIV seroconversion rate per 100 person-years in IVDUs: from seven in 1985 to 2.4 in 1987.[8] It is very difficult to evaluate properly the impact of behavioral change among IVDUs in Amsterdam, by comparing it with studies being done in other countries. Generally, because large segments of the total population of IVDUs are hard to reach, very little is known about the representative-

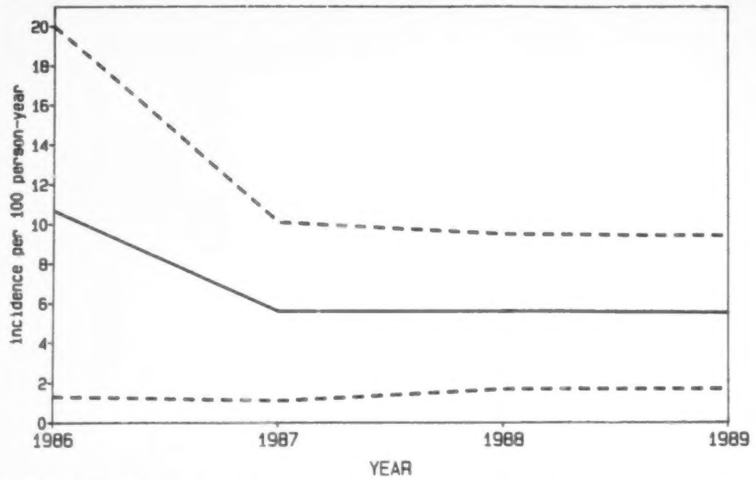

FIGURE 1—Incidence density and 95% confidence interval of HIV-antibody seroconversion in IVDU per year, 1986–89

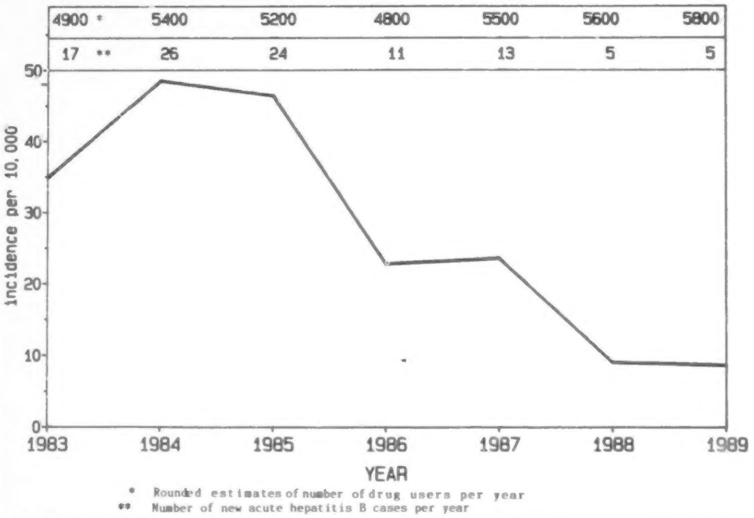

FIGURE 2—Estimated incidence of acute hepatitis B per 10,000 drug users in Amsterdam, The Netherlands, 1983–89

ness of IVDU study samples; ours is no exception. Participants were self-selected and follow-up was poor; only 57 percent of HIV-antibody negative IVDU at entry returned for at least one follow-up visit. Continued participation in the study may be of more interest to those IVDUs who have not modified their risk behavior and therefore may suspect a change in their serostatus since their last test. For this reason we may be overestimating HIV incidence in IVDUs in Amsterdam when generalizing from this group. On the other hand, we have evidence that behavioral change did occur especially in those drug users who took part in the follow-up study.[3]

We found rather stable HIV seroprevalences over the years, both for the crude prevalences and after attempting to correct for the influence of selection biases following from our sampling procedures. Stable HIV seroprevalences among IVDUs in recent years have been reported from many cities in North America and Western Europe.[8–16] The interpretation of this phenomenon, however, and especially measuring the impact of behavior change by monitoring seroprevalence, is very difficult since many factors that affect the general IVDU population and that are generally not well recorded—for example loss of seropositives for various reasons (mortality, hospitalization, moving, cessation of drug use, etc.) and entrance of new seronegative injectors—have to be taken into account. As appears from our data and as was reported before from Manhattan, New York City,[9] a stable seroprevalence is still compatible with a rather high incidence.

Throughout the study period the same technique was applied to estimate the number of drug users in the city and reporting requirements for acute hepatitis B remained the same. We therefore consider it unlikely that the marked decrease in acute hepatitis B observed in drug users is an artefact, i.e. the result of a change in these procedures. From the United Kingdom a similar decrease in acute hepatitis B incidence in drug users since 1985 has been reported.[17]

In conclusion, we found a modest decrease in HIV incidence among IVDUs participating in our follow-up study which correlates with the earlier reported behavioral change in this group.[3] The decline in acute hepatitis B incidence is a convincing indicator of effective behavior change. The largest drop in hepatitis incidence appeared before 1987, a period about which we have very limited data on HIV prevalence and incidence. Possibly a parallel reduction occurred in HIV incidence in that period that we were not able to measure. Nevertheless, recent HIV incidence rates still appear to be disturbingly high, indicating that transmission among this group is continuing. ☐

ANA Releases Draft Report for Health Care Reform

After nearly two years of effort devoted to the development of a reform plan for health care delivery in the nation, the American Nurses' Association (ANA) has released a working draft of the report "Health Care Reform: An Agenda for Action" for review and comment. ANA President Lucille Joel describes the plan as achievable, realistic and cost-effective.

ANA expects to release the report to the public early in 1991, after study by the association's 53 constituents, elected and appointed officials, participants in the ANA Nursing Organization Liaison Forum, and the Tri-Council for Nursing. In this way, ANA expects that the report will reflect an agenda on behalf of the entire nursing profession.

Joel says, "Nursing's plan for health care reform represents a massive effort on behalf of the entire profession to clearly lay out what the nation's nurses believe to be a plan for the delivery of health care services that best meets the needs of the public." The plan offers solutions to many problems affecting the US health care system, including access to care; the lack of or misuse of appropriate providers, settings and delivery arrangements; equitable and affordable financing; and stronger cost controls.

Recognizing that cost and revenue estimates are critical components of health care reform and that adequate funding sources must be available, the ANA plan provides an example for financing. Unique characteristics proposed in the working draft include:

- federal standards to assure access by all to basic levels of health services through public and private health service plans;
- implementation of the plan through incremental steps to be completed by the year 2000 with an initial focus on pregnant women as well as infants and children;
- renewed emphasis on schools, places of work, the home, and other community settings for the delivery of care; and
- reliance on multiple payors—individuals, employers and government—to finance the reformed system.

ANA's Board of Directors planned to review comments received from the nursing community at its December meeting. After approval by the board the plan will be prepared for wide dissemination. For further information, contact ANA, 2420 Pershing Road, Kansas City, MO 64108.

Predictors of Successful Aging: A Twelve-Year Study of Manitoba Elderly

Noralou P. Roos, PhD, and Betty Havens, MA

ABSTRACT

In Manitoba, Canada, a representative cohort of elderly individuals ages 65 to 84 (n = 3,573) were interviewed in 1971 and the survivors of this cohort were reinterviewed in 1983. This analysis assesses the determinants of successful aging—whether or not an individual will live to an advanced age, continue to function well at home, and remain mentally alert. Over 100 separate indicators of demographic and socioeconomic status, social supports, health and mental status in 1971 were available as potential predictors of successful aging. Indicators of access to health care over the period 1970–82 and indicators of diseases over this period were also available as predictors.

Those who aged successfully were shown to have greater satisfaction with life in 1983 and to have made fewer demands on the health care system than those who aged less well. Despite the large number of potential predictors of successful aging which were examined, only age, four measures of health status, two measures of mental status, and not having one's spouse die or enter a nursing home were shown to be predictive of successful aging. (*Am J Public Health* 1991; 81:63–68)

Introduction

The elderly are not a homogeneous group. Some are beset by multiple chronic and/or acute conditions and spend considerable time in hospital. Still others, especially women, live a very long life but are afflicted by increasing frailty or declining mental status, passing their last years in nursing homes. Some elderly manage to avoid all of these scenarios, maintain themselves independently in the community and are described as "aging successfully."[1,2]

While other investigators have attempted to study successful aging, our analysis is unusual in its longitudinal design, its large representative sample, and in focusing on successful aging of an already elderly cohort. It addresses three questions:

1. What proportion of an elderly cohort will age successfully?
2. What are the health care expenditure patterns associated with successful aging?
3. Which characteristics of individuals predict successful aging? (From among all those interviewed in 1971, who will successfully age? And among those who survive to 1983, what are the factors which predict successful aging?)

Methods

In 1971 a large (N = 3,573) representative sample of individuals ages 65–84 living in the community was interviewed as part of the Manitoba Longitudinal Study on Aging.[3,4] In 1983 and 1984 survivors of this cohort were reinterviewed. In addition, the health care expenditures of this cohort over the period 1970 through 1983 were available from administrative records of the universally insured provincial health care program.

The sample was selected as follows: 2.5 percent of the residents of urban areas and 5 percent of the residents of nonurban areas. Analyses were reweighted by the sampling proportions within strata to reflect population figures. A place of residence variable (urban/not) was included in each multivariate model to control for sampling fraction.

Individuals were excluded from the analysis if they were not resident in the province (as judged by coverage in the health care system) for the period of the study, 1970 through 1983 or until death (310); if they were alive and resident in the province in 1983 but not reinterviewed (147); or if the 1971 or 1983 interview was conducted entirely through a proxy (101). (Proxy interviews were used primarily where individuals were too ill or confused to respond.) Native Manitobans (90) were also excluded from the analysis. The final sample for this analysis included 2,943 elderly. A comparison of baseline characteristics of those included and excluded in the study found no difference in age and sex or self-reported health status. However, the interviewer was significantly

more likely to rate the respondent's mind as steady or strong in general for those retained in the study.

Successful aging was defined using the 1983 reinterview as follows:

- Alive in 1983.
- Not resident of a nursing home in 1983.
- Did not receive more than 59 days of home care services in 1983.
- In the 1983 interview:

Rated health excellent to fair.
Not dependent in any activities of daily living (getting in and out of bed, dressing, bathing, eating, using stairs).
Did not use a wheelchair.
Did not need help in going out doors.
Able to walk outdoors.
Scored seven or more correct answers on Mental Status Test.

Interviewer judged respondent's state of mind to be steady and strong or a bit weak only after some interview time had elapsed.

Cause of death was taken from death certificates. Less than 1 percent of the individuals (N = 26) died of accidents, poisonings, or violence and therefore lost the chance to age successfully.

Claims data have been shown to provide a highly accurate, reliable, and valid representation of health care use.[5,6] Claims were used to estimate health care expenditure patterns associated with healthy aging over the 14-year period 1970–83 (or until death). The following types of utilization were tracked: days spent in hospital (with days spent in intensive care treated separately); days spent in nursing home; days enrolled in the home care program; all physician visits and surgical fees (for both inpatient and outpatient procedures).

Since nursing home services in Manitoba have been universally insured only since 1973, costs incurred by nursing home residents prior to July 1973 were estimated as described elsewhere.[7] Since September 1974, home care services in the province have also been universally provided at no charge to consumer.

Manitoba hospitals and nursing homes are funded on the basis of global budgets.[8] An estimate of mean costs per day in hospital ($322) and nursing home ($49) was calculated by dividing total Manitoba Health Services Commission payments (including capital repayment) to hospitals and to nursing homes in fiscal 1984 by the number of days of care produced that year by these institutions. The cost of a day in intensive care was estimated to be $1,610, five times the cost of a hospital day. Although per diem costs escalated markedly in both the hospital and nursing home sectors over the time period studied, constant dollar costs were used. The estimate of home care costs per day ($4) were derived by dividing service costs per user over a six-month period by the 182 days in that period.[9] Total payments for physician visits and consultations were divided by the total numbers of visits to obtain an average cost per visit ($17). All costs are in constant 1984 Canadian dollars.

Variables available from the 1971 interview represent potential predictors of successful aging, while diagnoses made during physician visits over the period 1970 through 1982 and variables constructed from administrative records recording events occurring to spouse (death or admission to nursing home) during this same period are potential factors associated with successful aging. Thus predictors of successful aging may include characteristics of the individual's demographic, ethnic and cultural background, socioeconomic characteristics, and characteristics of the support network. The individual's mental status was also assessed in 1971, as well as satisfaction with life, and several characteristics of health status. Factors studied for association with successful aging include changes in the individual's support network over time (whether the individual's spouse predeceased him or her and whether the spouse entered a nursing home prior to the interviewee's death or 1983).

The extent to which specific diseases pose threats to successful aging was examined using both self-reports in 1971 and claims-derived measures of physician contact for five conditions judged to place an elderly individual at "risk for recovery."[10] The Manitoba Cancer Registry was used to determine whether the individual had been diagnosed as having cancer (other than skin). Whether individuals had regular contacts with physicians (and therefore would be available for the early detection and treatment of disease) was measured by the percent of years the individual was alive between 1970 and 1982 during which one or more (or two or more) visits were made to physicians. (See Appendix for a complete listing of predictor variables.)

Two dependent variables were examined: successful aging (yes-no); and successful aging versus survival to 1983 in a dependent state.

In the analyses, using the first dependent variable, all individuals sampled were used to determine which variables were predictive of successful aging. The second analysis examined the association between all dependent variables and successful aging among those who survived to 1983.

Because of the large number of independent variables, a two-step process was followed for each group of variables (see Appendix for grouping). First, the relation of each variable to each dependent variable was tested by univariate analyses. A forward step-wise fitting algorithm for the multiple logistic regression model was used to determine which variables among each group of predictor variables made a contribution to each model at a p value level of 0.05. Age and sex were included in every model. From among those variables within a set which were substantially correlated with one another (i.e. absolute value of Pearson correlation coefficient .5 or greater) only one was selected for modeling. The variables which made the most contribution to model fit, or, where there was little difference, the variables most commonly used in previous studies were selected.

A final multiple logistic regression model was fit including the variables from each set selected as described above. Contributions to the model of the combined effect of 1) sex and income, 2) sex and spousal death/nursing home entry, 3) income and spousal death/nursing home, were assessed by including interaction terms in the model.

The data were randomly split with one-half of the records used to develop the models and to estimate the coefficients of the logistic regression models.[11] The final model was tested on the other half of the records to see if the same variables entered the model and whether the coefficients were estimated in similar magnitude. All data have been pooled for presentation since the larger sample provides more stable estimates of the coefficients.

Results

By our definition, 20 percent of those individuals ages 65 to 84 interviewed in 1971 were judged to have successfully aged in 1983, 22.6 percent were alive but dependent, and 57.5 percent were deceased (Table 1). Males were more likely to be deceased by 1983 than females. Although females ages 65 to 74 were somewhat more likely to have aged success-

TABLE 1—Characteristics of Individuals in 1983 by Age in 1971

	Age in 1971				
	65–74		75–84		
Characteristics of Individual in 1983	Male %	Female %	Male %	Female %	All %
Has successfully aged	24.0	31.5	7.0	5.9	20.0
Alive but dependent	19.9	29.8	12.3	24.4	22.6
Deceased	56.1	38.7	80.7	69.8	57.5
Number (N)	908	930	521	584	2943

TABLE 2—Satisfaction with Life in 1983 in Those Defined as Successfully Aged versus Those Alive but Dependent

	Characteristics of Individuals in 1983		
Satisfaction	Aged Successfully	Alive but Dependent	N
In 1983, how would you describe your satisfaction with life in general at present?			
Excellent	69.6	30.4	182
Good	60.5	39.5	556
Fair	46.9	53.1	193
Poor-Bad	18.1	81.9*	40

*Mantel Haenszel Trend Test: p < .001

TABLE 3—Total Health Care Expenditures over Period 1970–83 by Individuals' Differing 1983 Health Status

	Characteristics of Individuals in 1983			
	Aged Successfully	Alive but Dependent	Deceased	All
Total Health Resource Use* 1970–83 or to Time of Death (%)				
0–$10,000	67.7	30.5	23.5	33.9
10–25,000	20.7	18.4	22.1	21.0
25–50,000	9.5	19.6	21.8	18.8
50–100,000	2.0	14.0	17.0	13.3
$100,000 or more	0.1	17.5	15.7	13.0
Mean Resource Use per Individual (in $ over Period 1970–83 or to Time of Death)				
Total use ($)	10304	53906	50643	43354
Use per year lived ($)	736	3850	5955	4441
Number	583	666	1694	2943

*Resource use is estimated in 1984–85 Canadian dollars as follows: $1,610 per day in intensive care, $322 per hospital day, $49 per nursing home day, $17 per physician visit, $4 per day on home care, and actual $ amount for surgical procedures.

fully than males, there was little difference in successful aging by sex in the older age group (p = .466). Recalculating the percentages in Table 1 (not shown) and focusing upon those who survived to 1983 shows no difference in the percentage of females versus males in the youngest group who successfully aged (p = 0.172). However, among survivors in the oldest age group, males were more likely to successfully age than were females (32.7 percent versus 18.0 percent, p = 0.006).

Remaining independent (the definition of successful aging) is associated with a higher level of satisfaction with life in older age (see Table 2). Separate comparisons by age confirmed this relationship (data available on request to author). However, maintaining functional independence is not a guarantee for being satisfied with one's life in advanced old age. Moreover, losing one's independence is not necessarily judged a disaster. Among those reporting their satisfaction with life to be excellent, 30.4 percent were classifed as "alive but dependent" in 1983.

Individuals who remained independent made markedly fewer demands on the health care system (Table 3). About two-thirds (67.7 percent) of those aging successfully used less than $10,000 worth of health care resources over the 14-year period 1970 through 1983, averaging $736 per year. In contrast, those who lived to 1983 in a more dependent state averaged $3,850 per year over the 14-year period. Those who died before 1983 had the highest resource use averaging $5,955 per year lived. Further analyses (not presented in Table 3) demonstrated that the low resource utilization patterns of those aging successfully were observed both for males ($768 per year lived) and females ($710) and were independent of age ($744 per year for those aged 65–74 in 1971 and $671 for those aged 75–84).

Table 4, using multivariate analysis, suggests that the most important factors distinguishing those who successfully aged from all others interviewed in 1971, apart from age, were: bad outcomes occurring to a spouse, self-reported health in 1971, retirement because of poor health, not developing cancer or diabetes, and not having good mental status. Females were no more likely to age successfully than were males.

Factors which distinguish those who successfully aged from those who survived to 1983 but were functionally dependent are shown in Table 5. After controlling for age, self-rated health was again a strong predictor of successful aging. Individuals who did not have diabetes were also more likely to age successfully, although cancer had no similar impact. The odds of successful aging were decreased if one's spouse died or was assessed for or placed in a nursing home.

Discussion

Successful aging has been defined in terms of an individual retaining the ability to function independently.[1,2] Those who age successfully remain out of institutions and do not have continuing input from a

TABLE 4—Adjusted Relative Odds of Successful Aging as Estimated by the Multiple Logistic Regression Model. I. Comparing Those Who Age Successfully with Those Who Died or Became Functionally Dependent by 1983

	Relative Odds Estimate	95% Confidence Interval
Age of Individual in 1971		
65–69/80–84	28.8	(13.9, 59.7)
70–74/80–84	12.7	(6.1, 26.3)
75–79/80–84	4.5	(2.1, 9.7)
Sex		
female/male	1.2	(1.0, 1.5)
Spouse Assessed/Placed in Nursing Home (1971–82)		
yes/others	0.2	(0.1, 0.5)
Spouse Died 1971–82		
yes/others	0.4	(0.2, 0.6)
Self-Rated Health 1971		
excellent/poor bad	7.0	(4.0, 12.4)
good/poor bad	4.0	(2.4, 6.8)
fair/poor bad	2.4	(1.4, 4.2)
Reason for Retiring (1971)		
poor health, compulsory/others	0.6	(0.5, 0.8)
Cancer (1970–82)		
no/yes	3.5	(2.4, 5.1)
Had Physician Visit(s) for Diabetes (1970–82)		
no/yes	1.7	(1.3, 2.5)
Interviewer Assessed State of Mind (1971)		
steady and strong/else	2.5	(1.4, 4.6)
Score on Mental Status Index (1971)		
High score (9 or 10)/Lower score (0–8)	1.6	(1.1, 2.4)

Model Chi-Square = 514 with 15df. Region of residence was included in the model to control for sampling fraction. Logistic regression results were based on comparing 583 individuals who aged successfully with 2,350 individuals who died or became functionally dependent by 1983. The score on the mental status index, not having diabetes, and rating one's health as fair, reached the 0.05 level of significance in only one of the split half models and the final model.

home health agency. They remain mobile and competent in all the activities of daily living. While these individuals defined their health status in 1983 as fair or better, we deliberately did not label these individuals the "healthy aged." Healthy implies the absence of disease and further, individuals with the "same disease" may have a different sense of well-being and ability to function.[12]

Our results are interesting not only because of the variables they include, but also for the variables which they do not include. None of the measures of socioeconomic status were significant in the final models, even though the measures available in 1971 were extensive. Also, an index combining high scores on the education, occupation and income variables was constructed but did not prove significant.

Two recent studies[13,14] have reported that low incomes are associated with poor health outcomes for Canadians despite universally insured medical and hospital care. Guralnik and Kaplan[12] also found income predictive of a high level of functioning in the 19-year follow-up of Alameda County residents. Two factors may help to account for our contradictory findings compared to these earlier studies. The income effect may decrease with age because: not as many poor people as others survive long enough to be classified as "old"; the income gradient among the elderly may narrow with government transfer payments improving the lot of the poor, while advancing age is depleting the resources of the wealthy. Haan, *et al*,[15] compared age-specific mortality rates among White Alameda County residents of poverty and non-poverty areas. While in the younger age groups the mortality rates in poverty areas were much higher, among those ages 65 and older, there was essentially no difference. Finally, the one group in Canadian society which is most economically disadvantaged, Native Canadians, were excluded from the analysis.

This study presents strong evidence that regular contact with physicians, even among elderly individuals (one of the highest risk groups in the population), is not related to successful aging. Regular contact with the health care system was measured with a high degree of accuracy. Neither the percentage of years in which individuals made one or more visits, nor the percentage of years in which two or more visits were made, was associated with successful aging.

Many measures of disease and functional status were not useful predictors of successful aging. None of the measures of poor functional status in 1971, including indicators that an individual needed help in the activities of daily living or in instrumental activities, none of the self-reported health conditions (including stroke, arthritis, etc.) and only one of the conditions for which physician visit data were available (diabetes) was negatively associated with successful aging.

These findings are contrary to most preconceptions and to some literature. The National Institute of Mental Health's Human Aging II Study,[16] a longitudinal follow-up of a small number of very healthy males, found even asymptomatic disease was negatively predictive of longevity. However, that study focused on longevity alone and longevity is only one (albeit an important) aspect of successful aging.

Having cancer was negatively associated with successful aging but primarily influenced longevity; people with cancer were less likely to live long enough to age successfully by our criteria. However, if such individuals did survive to 1983 (6.7 percent of those surviving to 1983 had cancer), they were just as likely to have aged successfully as those without cancer.

Since age is strongly related to mortality, odds ratios for categories associated with successful aging are greater for the model whose comparison group included decedents (Table 4). The magnitude of the odds ratio for the female sex decreased somewhat from model one to model two (Table 5) reflecting the fact that, although more females may survive, their chance of aging successfully appears to be lower than that for males who survive.[17] A comparison of self-rated health in the two models suggests the distribution of self-rated health in 1971 among those who subsequently died was similar to that among those who remained alive but dependent.

Previous work in Manitoba demonstrated that self-rated health was a predictor of mortality over a six-year period independent of objective health status[18] and this relationship has been confirmed by

TABLE 5—Adjusted Relative Odds of Successful Aging as Estimated by the Multiple Logistic Regression Model. II. Comparing Those Who Age Successfully with Those Who Were Alive in 1983 but Dependent

Specification of Variable	Relative Odds Estimate	95% Confidence Interval
Age of Individual in 1971		
65–69/80–84	11.5	(5.3, 25.0)
70–74/80–84	5.6	(2.6, 12.3)
75–79/80–84	2.7	(1.2, 6.2)
Sex		
female/male	0.8	(0.6, 1.0)
Spouse Assessed/Placed in Nursing Home (1971–82)		
yes/others	0.1	(0, 0.4)
Spouse Died 1971–82		
yes/others	0.4	(0.3, 0.8)
Self-Rated Health 1971		
excellent/poor bad	5.5	(2.9, 10.6)
good/poor bad	3.0	(1.7, 5.5)
fair/poor bad	2.2	(1.2, 4.0)
Reason for Retiring (1971)		
poor health, compulsory/others	0.7	(0.5, 0.9)
Cancer (1970–82)		
no/yes	1.0	(0.6, 1.7)
Had Physician Visit(s) for Diabetes (1970–82)		
no/yes	1.5	(1.0, 2.2)
Interviewer Assessed State of Mind (1971)		
steady and strong/else	1.9	(1.0, 3.9)
Score on Mental Status Index (1971)		
High score (9 or 10)/Lower score (0–8)	1.9	(1.2, 2.8)

Model Chi-Square = 208 with 15df. Included in the model was region of residence to control for sampling fraction. Logistic regression results based on comparing 583 individuals who aged successfully with 662 individuals who were alive in 1983 but dependent. Age 75–79, having a spouse who died, retiring because of poor health, having a visit for diabetes, reporting fair health and having a high score on the mental status index, reached the 0.05 level of significance in only one of the split half models and the final model.

others.[19] The present study extends these findings by demonstrating that self-rated health is not only an important predictor of mortality over the longer 12-year period, but is also one of the few factors associated with successful aging among those who survive. Muller[20] suggested that the predictive contribution of self-rated health could be partly due to Mossey and Shapiro's including indicators developed from utilization data in their measure of objective health status. She suggested pessimism and depression might be the actual causal factors. Although measures of life satisfaction in 1971 were predictive of successful aging in early models, they made no contribution here to the final models which included the self-rated health measure.

There were measures unavailable to this project which might have made useful contributions. The most obvious limitation of the data was the lack of biological measures of function (blood pressure, etc.) and the lack of measures of health practices (smoking history, alcohol consumption, regular physical activity, etc. although the latter could be approximated by the questions pertaining to leisure time activities). The Alameda County study found individuals with more low risk practices to have lower mortality rates.[21] The Framingham Study, after 21 years of biennial observations, also reported that alcohol intake, smoking, ventricular rate, and education were related to good functioning status for men although, for women, the only significant predictor other than age was education.[22]

In conclusion, a significant group of elderly do age successfully. These individuals express more satisfaction with their lives and incur substantially fewer health expenditures than other elderly. Individuals at particular risk of not aging successfully include those with poor self-assessed health, whose spouse has died, whose mental status is somewhat compromised, who developed cancer, and those who are forced to retire or retire because of poor health. ☐

Acknowledgments

This research was supported by grant (6607-1440-57) from the National Health Research and Development Program (NHRDP). The 1971 interview was funded by the Government of Manitoba, Department of Health, with the 1983 interview funded by NHRDP grant (6607-1302-06) and the Government of Manitoba, Department of Health. The assistance of Robert Tate, Carmen Steinbach, Bogdan Bogdanovic, Betje Jacobs, and Debbie Molina is acknowledged with thanks. The authors are indebted to the Manitoba Health Services Commission, the Manitoba Cancer Treatment and Research Foundation, and the Manitoba Department of Vital Statistics which helped make this research possible. Interpretations of the data are the authors' own.

APPENDIX

Variables Available to the Analysis
(All Items from 1971 Interview Except as Indicated)

- **Ethnicity and Cultural Characteristics of Individual**
  - National descent
  - Language spoken
  - Date of arrival in Canada
  - Language of interview

- **Socioeconomic Characteristics of Individual**
  - Level of education attainment (number of years or grades completed in school)
  - Major occupation when employed
  - Current employment in major or other occupation
  - Major reason for continuing working (if applicable)
  - Total monthly income (a total of income reported from three sources: own resources—wage, rents, interest, etc.; pensions or allowances; other sources—children, etc.)
  - Disposable income (calculated by subtracting monthly expenses from monthly income)
  - Percent of income from private sources
  - Whether income satisfied current needs
  - Whether income would satisfy future needs
  - Would extra income be spent on food, medical needs, etc.
  - Ownership of current residence
  - Characteristics of residence
    - Heating satisfactory, lighting satisfactory, complete bathroom available, bathroom sharing, a room of one's own?
    - Residence in a senior citizens' housing unit

- **Characteristics of Individual's Social Network**
  - Marital status
  - Living arrangements (with spouse, with spouse and others, other)
  - Number of relatives, amount of contact with them and "nearness"
  - Frequency of contact with neighbors, friends
  - Death of spouse between 1971 interview or person's death or December 31, 1982*
  - Spouse assessed for or entered nursing home during same period*

- **Individual's Mental Status**
  - Score on 10 question mental status test[23]
  - Frequency of forgetting names of friends or relatives, time of day. How quickly recalled?
  - Interviewer's assessment of respondent's:
    - —state of mind (steady and strong to weak or unsteady)
    - —attitude (friendly to hostile)
    - —comprehension of questions (satisfactory to unsatisfactory)

- **Satisfaction with Life**
  - In general
  - Score on 20 question Life Satisfaction Index "A"[24]

- **Individual's Health Status**
  - Self-reported health: "For your age, would you say your health is excellent, good, fair, poor or bad?"
  - Reporting any of 15 health problems including diabetes, chest problems such as asthma or emphysema
  - Under treatment for any of these conditions
  - Amount of time in bed at home because of illness in last year: none, less than one week, one week to a month, more than a month
  - Help required in basic activities of daily living (getting in and out of bed, dressing, bathing, eating, using stairs)
  - Number of activities requiring help from someone outside the house (light housework, making tea, preparing a hot meal, shopping, laundry, heavy housework, financial affairs)
  - Number of activities requiring help from someone inside or outside the house (nursing care, cutting toenails, going out of doors, watching TV or reading)
  - Required attention of physician or nurse when last sick
  - Moved because of ill health
  - Retired because of poor health
  - Living in a senior citizen housing unit (individuals tend to move to these rental units when they have difficulty maintaining themselves at home usually for health and/or economic reasons)
  - Unmet health care needs for eyeglasses, hearing aid, false teeth, cane, special shoes, wheelchair or medicine
  - Mean number of physician visits (per year alive) for conditions identified as increasing an individual's "risk of not recovering from an illness"[10] e.g. angina, arthritis, arrhythmia, diabetes, hypertension over period 1970–82*
  - Number of above listed conditions for which made one or more physician visits (per year alive); for which made two or more physician visits (per year alive)*
  - Cancer (excluding skin cancer) diagnosed 1970–82**

- **Participation in Leisure Time Activities**
  - 21 alternatives including visiting, telephoning, listening to radio or TV, work, etc.
  - Which activities are most important

- **Access to Care**
  - Difficulty getting to see a doctor/dentist because of transportation, language problems or distance
  - Percentage of years alive in which one or more visits to physician were made; in which made two or more visits, 1970–82*

Does Maternal Tobacco Smoking Modify the Effect of Alcohol on Fetal Growth?

Jørn Olsen, MD, PhD, Altamiro da Costa Pereira, MD, and Sjurdur F. Olsen, MD

ABSTRACT

Smoking and drinking habits were registered by a self-administered questionnaire in 36th week of gestation in 11,698 pregnant women, more than 80 percent of all such women in two Danish cities 1984–87. Alcohol consumption of 120 g/week or more was associated with a greater reduction in the average birthweight in the babies of smokers than of non-smokers (about 40 grams for the non-smokers and about 200 grams for the smokers). This is particularly striking considering that the average birthweight for smokers is lower than for non-smokers. A birthweight difference of more than 500 grams was found between babies of mothers who neither smoked nor drank and mothers who smoked and drank heavily. Our data suggest that women's smoking habits should be taken into consideration when giving pregnant women advice about drinking. (*Am J Public Health* 1991; 81:69–73)

Introduction

It has been known for many years that smoking during pregnancy reduces fetal growth[1] and it is also well established that growth retardation is part of the fetal alcohol syndrome.[2] Tobacco smoking relates to fetal growth and birthweight in a dose-response manner[1] but the association with alcohol consumption remains less clear. In a recent publication,[3] only alcohol intake of 120 grams or more per week was associated with low birthweight, and it was suggested that health education should be directed mainly toward mothers who drink 100 grams of alcohol or more per week. Another recent study[4] found that alcohol had an effect on birthweight only in smokers.

The purpose of our study was to investigate whether it is reasonable to assume a threshold for the effect of alcohol on birthweight and other growth parameters according to smoking habits.

Methods

Detailed information was collected on drinking and smoking habits of pregnant women attending the midwife centers in Odense and Aalborg, Denmark during their 36th week of gestation, from April 1984 to April 1987. The mothers sent a completed questionnaire directly to the Department of Social Medicine, Odense University. The medical records and questionnaires were given a study number which was not related to the personal identification number. After delivery, obstetrical information was extracted from the medical records and linked to the questionnaire data by means of the study number.

More than 95 percent of all pregnant women in two defined geographical areas at the 36th week of gestation were covered, for a total of 13,815 women. After excluding multiple births, data were available from the questionnaires and medical files for 11,850 women. Most of the non-responders failed to answer reminders, and some left the study area before delivery so that no data were available regarding the child. Also excluded were 152 women who gave birth before the 36th week of gestation; the data file thus consisted of 11,698 women.

Detailed questions were asked concerning beer, wine, spirit, coffee, and tea consumption before and during pregnancy. The number of alcoholic drinks per week was calculated; each drink was considered to contain 12 grams of absolute alcohol according to normal quantities of alcoholic beverages per glass (or bottle of beer) in Denmark. The data on smoking and drinking were self-reported and referred to average consumption during the first 36 weeks of gestation.

Data on gestational age, weight increase during pregnancy, placental weight and measurements of the child (weight, length and head circumference) were recorded from the mothers' and infants' hospital records. All were measured blind to knowledge of questionnaire data. All deliveries took place at one central hospital in each region. The midwives who car-

ried out the recording had a comparable training and conducted the assessments in a standardized way. The study was part of a large community trial among pregnant women in Denmark.[5]

In the data analysis, multiplicative as well as additive models have been used (logistic regression and analysis of variance). The variables which were most closely associated with alcohol consumption and which were known to be predictors of fetal growth were included as confounders.

Results

Table 1 displays the characteristics of the participating women. Smoking and drinking habits during the first 36 weeks of gestation are shown in Table 2. Thirty-five percent were non-smokers who drank 1–29 grams of alcohol per week. Almost 200 women reported that they consumed 120 grams (10 drinks) or more per week and 832 indicated a smoking history of 15 cigarettes or more per day. The proportion of newborns with a birthweight of less than 2500 grams varied widely with a tendency to correlate with the frequency of alcohol and tobacco use.

Most newborn measures decrease with increasing cigarette and alcohol intake. Among smokers the decrease associated with alcohol is greater than among non-smokers (see Table 3).

In Table 4, the results of the analysis of variance of the data shown in Table 3 are presented. Among non-smokers, alcohol consumption was found to be statistically significantly associated with placental weight and birthweight (test for trend). Among smokers of 1–9 cigarettes, alcohol was associated with birth length, and in the subgroup of heavy smokers alcohol was significantly associated with all measures (except birth length).

All of the variables in Table 4 depended upon the duration of pregnancy and in two additional analyses of variance, confounding by gestational age was addressed (data not shown). In one model, gestational age was included as a covariate and, in another model, the analyses were restricted to women who gave birth between the 39th and 41st weeks of gestation. In these analyses, the adjusted differences from the mean were in the same direction but usually a little smaller. A statistically significant association between alcohol consumption and placental weight was still found for non-smokers. In the group of moderate smokers, significant associations were found for placental weight, birthweight and birth length (but not in the restricted analyses). In the group of heavy smokers, all associations remained statistically significant at the 0.05 level (except in the restricted model with birth length).

Clear "dose-response" relationships were not seen in any models in Table 4, except for birthweight among heavy smokers. However, random variation due to small numbers in the sub strata should be taken into consideration. Among heavy smokers, women who drank more than 30 grams of alcohol per week had a substantially lower birthweight. This is particularly striking considering the generally low mean for that group of women.

Table 5 presents odds ratios for low birthweight according to alcohol consumption compared with frequency of low birthweight for non-drinkers. Each smoking stratum represents a separate analysis. A two- to three-fold increase was seen for all consumers of 120 grams of alcohol or more per week. The marginal values in the table show an excess risk of low birthweight in the group of "heavy drinkers" only. The prevalence of low birthweight increased steadily with increasing cigarette consumption, as can be seen in the right hand column.

All analyses in Table 5 were repeated with the subset of women who gave birth in the 39th–41st weeks of gestation and weight increase during pregnancy was also included in the models. By restricting analyses to deliveries at term, a four-fold increase of low birthweight was found for consumers of more than 120 grams of alcohol per week (data not shown).

After controlling for average alcohol consumption, no association between binge drinking and any of the pregnancy outcome measures was seen (data not shown).

According to the present data set, neither the additive nor the multiplicative model of interaction between alcohol consumption and tobacco smoking on any of these measured outcomes fitted the data very well, despite the fact that both models were acceptable according to formal statistical testing of interaction terms.

Discussion

Birthweight was closely correlated with the combined exposure to alcohol as

TABLE 1—Age, Parity, Gestational Age at Birth and Weight Increase during Pregnancy for 11,698 Participating Women

well as smoking, but a number of limitations of the study should be kept in mind. The sample was truncated at 36 weeks, and therefore precluded study of babies born at earlier gestation. Since data on smoking and drinking habits are self-reported, intake of alcohol especially was likely to be underreported, particularly high consumption levels. For this reason, no estimates were made for alcohol consumption of more than 120 grams per week. Few women indicated no drinking at all during pregnancy, which agrees with our impression that Danish women usually report moderate and socially acceptable levels of drinking without hesitation.

It is likely that the heavy drinkers were more prevalent among non-responders than responders, but since exposure data were collected prior to the deliveries, bias is not a serious problem. Nevertheless, the effects shown may be underestimates.

Sulaiman, *et al*,[3] suggested that health education during pregnancy should be directed toward mothers who drink more than 100 grams of alcohol per week since no statistically significant effect was seen below this level. However, that study was rather small with only a few women consuming more than 100 g absolute alcohol per week. Lumley, *et al*,[6] did not detect any harmful effect on fetal outcome of alcohol consumption during pregnancy at levels below two glasses a day. Our data indicate that health education should take smoking habits into consideration when giving advice about alcohol use during pregnancy. If pregnant women do not give up smoking while pregnant, a much lower level of alcohol intake should be aimed at. Furthermore, it must be taken into consideration that only a limited set of potential adverse effects of alcohol or smoking combined have been studied. Martin, *et al*,[7] found that maternal alcohol intake, coupled with smoking, exerted an interactive and deleterious effect upon newborn learning.

Our data to some extent supported the findings that consumption of beer is more closely related to adverse outcomes of pregnancy,[3,9,10] but it is likely that the association was confounded by social factors not recorded in the study (data not shown). We cannot recommend that health education should address the types of beverages differently at present.

We found that the average consumption of alcohol was much more important than binge drinking (data not shown). However, this may not be true for other adverse outcomes of pregnancy. Keeping alcohol's teratogenic effect in mind,[2] it is still wise to warn against binge drinking while pregnant.

Kariniemi, *et al*,[11] found that maternal alcohol consumption only decreased the birthweight among female fetuses. However, no such effect was seen in our study (data not shown).

Low birthweight remains the most important determinant of perinatal mortality and impaired development. When alcohol consumption increases among women, one should be aware of the fact that combined exposure of both alcohol and tobacco may reduce birthweight to a substantial degree, as illustrated by the increased ORs of low birthweight. The difference in birthweight between the lowest level of alcohol and tobacco use and the highest levels was found to be more than 500 grams.

In a large scale study, Mills, *et al*,[12] found somewhat different effects than we did. In our data, heavy alcohol consumption seemed to have a stronger effect on birthweight among smokers than non-smokers, whereas this phenomenon was apparently absent in Mills' data. Like

TABLE 5—ORs (and 95% CI) of Low Birthweight (< 2,500 g) According to the Mother's Smoking and Drinking Habits during Pregnancy (logistic regression)

Smoking* Status (Daily)	Alcohol in g/Week						Adjusted for Alcohol
	0	1−	30−	60−	90−	120+	All
0	1.0	0.8 (0.5–1.3)	0.9 (0.5–1.6)	0.8 (0.3–1.9)	0.5 (0.1–3.8)	2.2 (0.7–6.5)	1.0
1–9 cigarettes	1.0	0.9 (0.5–1.6)	0.6 (0.3–1.4)	0.5 (0.1–1.7)	— —	2.7 (0.9–8.0)	2.2 (1.7–3.0)
10+ cigarettes	1.0	0.8 (0.5–1.3)	0.6 (0.3–1.1)	0.9 (0.4–2.2)	1.6 (0.6–4.1)	2.1 (0.8–5.2)	3.4 (2.6–4.3)
Adjusted for smoking All	1.0	1.0 (0.7–1.3)	1.0 (0.7–1.5)	0.9 (0.5–1.5)	1.1 (0.5–2.5)	2.7 (1.5–4.8)	

*Logistic regression made on those subgroups of women according to smoking habits and on all in the study (marginal row and column) all analyses adjusted for age, school education, and parity. Alcohol and smoking entered the model as "dummy variables."

Mills, *et al*, we found little effect of low to moderate drinking among non-smokers but among heavy smokers reductions in average birthweight tended to appear already at an alcohol consumption of 30–59 g/week, and this pattern was not evident from the Mills data. One problem of comparing the two studies is that they did not use the same standards for alcohol and smoking exposure. More important, however, is the fact that our exposure data were collected at the 36th week of gestation while Mills' data were collected at the first visit in the first trimester. The generally stronger effects of alcohol on birthweight seen in our study may thus reflect the impact of a more relevant time period.

Although the significance of placental weight is disputed, it has been found to be a predictor of growth later in the childhood.[13] It is therefore interesting that alcohol consumption was found to be associated with relatively large reductions in average placental weight, although it should be kept in mind that the effects might have been exerted via fetal growth since birthweight and placental weight are closely associated.

Unfortunately, only some of the potential confounders could be controlled in this study. Nutrition, in particular, may be an important confounder in a study of alcohol consumption and fetal growth. Furthermore, it is likely that heavy drinkers may be less willing to follow prenatal care. Use of other drugs may be a confounder in some countries but it is unlikely in this sample.

The combined effect of alcohol and tobacco smoking should be taken into consideration when advising on health behavior during pregnancy. ☐

Pew Commission Advances Agenda Action for Nation's Health Professional Schools

The Pew Health Professions Commission met for the second time on November 7 and 8 in Washington, DC to advance 18 reform recommendations as part of a national Agenda for Action that addresses health care and educational issues challenging the nation's health professional schools. This agenda is built on an analysis of the current health care environment and the major forces and trends which will shape health care in the United States over the next 15 years.

The Commission's recommendations for discussion include a redefinition of the core science curriculum; a reorientation of the teacher-learning process; a shift in patient care training setting; a dissolution of the boundaries between the health professions; a redirection of faculty incentives; the creation of new governance and organizational arrangements; and a change in the orientation of the health professions from illness to health.

The Pew Commission will continue to refine the Agenda for Action over the next three months, and is expected to announces its final Agenda for Action in April 1991. The five objectives of the Pew Commission are to: establish a national Agenda for Action; develop appropriate policy recommendations for federal, state, professional and institutional agencies which will support implementation of the Agenda for Action; communicate the Agenda for Action; provide institutional change resources; and explore and fund demonstration projects at health professional schools across the nation.

The Pew Health Professions Commission is an outgrowth of the Future of the Health Professions project, a program of Duke University and The Pew Charitable Trusts. Over the past six years, The Pew Charitable Trusts has invested over $60 million of programming support in its Strengthening the Health Professions initiative and has secured an additional $40 million of leveraged support from other foundations for this initiative. For further information, contact Pew Health Professions Commission, Duke University Medical Center, 3101 Petty Road Suite 1106, Durham, NC 27707. Tel: (919) 490-6695; Fax (919) 489-5907.

Admission and Mid-Stay MedisGroups® Scores as Predictors of Death Within 30 Days of Hospital Admission

ABSTRACT

We examined the ability of MedisGroups, a severity measure based on clinical data abstracted from the medical record, to predict mortality 30 days following admission. MedisGroups measures severity both on admission and approximately one week into the hospital stay. The data base was a random sample of 20,985 admissions of Medicare beneficiaries with one of six conditions from 833 hospitals in seven states between January 1985 and May 1986. In all six conditions, higher admission and mid-stay severity scores were generally associated with higher risk of death. Across the six conditions, the R-squared values for predicting death using admission scores ranged from 0.01 to 0.16; R-squared values using mid-stay scores ranged from 0.03 to 0.34; and R-squared values from combining admission and mid-stay scores ranged from 0.05 to 0.41. Admission MedisGroups score was thus only modestly predictive of 30-day mortality. While the mid-stay score was more powerful, it may not be an appropriate severity adjuster to screen for quality using hospital mortality rates because it could be influenced by substandard care. *(Am J Public Health* 1991; 81:74–78)

Introduction

The Federal Government annually publishes mortality rates of almost 6,000 United States hospitals caring for Medicare beneficiaries. Although release of the mortality data is accompanied by numerous and appropriate disclaimers about their utility, the data are clearly intended to serve as an initial clue about the quality of hospital care, especially in an era of tightening cost constraints. The first hospital mortality statistics, published in March 1986, indicated that 142 hospitals had significantly higher death rates than predicted and 127 had significantly lower rates.[1] However, the facility with the most aberrant death rate (87.6 percent of Medicare patients dying compared with a predicted 22.5 percent) was a hospice caring for terminally ill patients. The government model had not adequately considered severity of illness.

This incident prompted a flurry of research activity, which has resulted in more sophisticated and methodologically sound approaches for producing the Medicare hospital mortality statistics.[2] Since 1987, the model has adjusted for patient age, secondary diagnoses, and a variety of other characteristics available in Medicare's administrative files; in addition, to control better for case mix and to accommodate the possibility that hospitals may perform better in some clinical areas than in others, condition-specific hospital mortality rates are also produced for selected diseases. However, data limitations remain. The information contained in Medicare's administrative files is confined to basic demographic, diagnostic, and procedural data not considered adequate to the task of severity adjustment by some critics.[3–7] The purpose of this research was to examine the performance of MedisGroups®, a severity measurement system based on data drawn from the medical record, as a predictor of mortality.

Methods

Description of MedisGroups

MedisGroups assesses severity as the risk of imminent organ failure independent of diagnosis, using information on key clinical findings (KCFs) abstracted from the medical record. MedisGroups is a registered trade name; the system is owned and marketed by MediQual Systems, Inc., in Westborough, Massachusetts. Severity is scored on admission on a five-point scale ranging from 0 to 4. For patients who remain hospitalized for the required period, a second severity rating is performed, the so-called "mid-stay" review, generating an appraisal of extent of "morbidity" (no morbidity, morbid, or major morbidity). MedisGroups is described in detail elsewhere,[8–11] and more information on the system is presented in an appendix. This description and the data used for this study pertain to the 1987 version of MedisGroups.

TABLE 1—Number of Cases by Admission MedisGroups Score and Percent Dying within 30 Days by Condition

Condition	Admission MedisGroups Score 0	1	2	3	4	Total
	Number of cases (percent dying within 30 days)					
Pneumonia or COPD	73 (1.4)	656 (2.9)	1,985 (9.0)	798 (28.7)	40 (67.5)	3,552 (12.8)
Coronary revascularization	1,073 (2.5)	1,228 (4.7)	782 (6.9)	273 (19.1)	11 (36.4)	3,367 (5.8)
Acute myocardial infarction	159 (6.3)	536 (8.2)	1,516 (15.4)	974 (40.9)	127 (80.3)	3,312 (23.8)
Congestive heart failure	119 (5.9)	396 (7.6)	1,792 (10.3)	1,143 (23.0)	74 (55.4)	3,524 (14.9)
Cholecystectomy	1,002 (1.2)	1,094 (1.4)	1,192 (2.8)	298 (5.4)	3 (33.3)	3,589 (2.2)
Prostate surgery	1,258 (0.6)	1,769 (0.8)	557 (2.5)	56 (7.1)	1 (0.0)	3,641 (1.1)

When MedisGroups is used for quality assessment, one strategy is to contrast the admission and mid-stay scores to determine whether the patient worsened, improved, or remained the same. For this purpose, admission scores of 0 and 1 are equated with no morbidity on the mid-stay review, while a 2 corresponds to morbid, and 3 and 4 correspond to major morbidity. In our analyses, we examined the predictive power of the admission MedisGroups score alone, the mid-stay review score alone, and the admission and mid-stay review scores considered together.

Description of the Data Base

The data base used for this study was created through the Health Care Financing Administration (HCFA) Health Standards and Quality Bureau. The data were collected by the peer review organizations (PROs) in Alabama, Arizona, Indiana, New York, Pennsylvania, Utah, and Wisconsin; the states were chosen to provide a geographically representative sample. Cases were randomly selected using administrative data on all Medicare beneficiaries, including disabled individuals younger than 65 years of age, admitted between January 1985 and May 1986. Selection was predicated on the presence of specified diagnostic and procedural codes. Final case selection was dictated by the PROs based on such factors as the availability of medical records. The analytic data base included 20,985 cases from 833 acute care hospitals across the seven states. The number of cases per hospital ranged from one to 480, with a median of 13 cases (mean = 25, standard deviation = 39) per hospital.

Conditions were selected based on their volume, relevance to Medicare beneficiaries (such as the elderly), and complexity of clinical issues raised in their care. The six study conditions were pneumonia or chronic obstructive pulmonary disease (COPD); coronary artery revascularization (including coronary artery bypass graft surgery and percutaneous transluminal coronary angioplasty); acute myocardial infarction; congestive heart failure; cholecystectomy; and prostate surgery (including transurethral and open prostatectomies). Cases in three conditions (pneumonia/COPD, acute myocardial infarction, and congestive heart failure) were selected using the principal diagnosis, while selection in the remaining conditions was based on procedure codes. Because of this selection approach, it was possible for cases chosen by diagnosis codes to have had a major procedure as well.

MedisGroups information and other selected clinical variables were collected by PRO abstractors trained by MediQual Systems, Inc. MediQual requires that reviewers achieve 95 percent exact agreement for items abstracted from the medical record; however, we did not independently confirm the reliability of the data. Data entry was performed by the PROs, then transmitted to MediQual Systems, Inc., for creation of a data tape for HCFA. The tape included admission and mid-stay scores, as well as the values for all KCFs.

Definition of Mortality

The data included date of death information from the Social Security administrative files, making it possible to identify deaths that occurred following discharge. The analyses focused on death within 30 days of admission, regardless of whether the death occurred in hospital. The 30-day figure is currently used by HCFA in producing its annual hospital mortality statistics, and it minimizes concerns about how differences in discharge practices across institutions and regions influence in-hospital death information.[2]

Statistical Methods

All analyses were performed within each of the six conditions. Each of the three models used the MedisGroups scores as categories indicated by dummy variables: admission score, five categories (0, 1, 2, 3, and 4); mid-stay review score, four categories (no mid-stay review, no morbidity, morbid, and major morbidity); and the joint categorization by both the admission and mid-stay scores, 20 categories (the five admission score classes crossed with the four mid-stay score classes). Given that each of our models contained only dummy variables as predictors, ordinary least squares and logistic regression methods produced exactly the same predicted probability of dying for every case (i.e., the same fraction dying among all cases in the same category). We looked at both the R-squared values and the C statistic from a logistic regression[12,13] to examine the ability of the three models based on MedisGroups scores to explain differences in death within 30 days of admission. However, only the R-squared values are reported here since no substantive differences emerged from looking at the C statistic.[10]

Results

Death Rates across MedisGroups Scores

The fraction of patients dying within 30 days of admission varied by condition,

TABLE 2—Number of Cases by Mid-Stay Review Score and Percent Dying within 30 Days by Condition

Condition	No Mid-Stay Review	Mid-Stay Review Score			Total
		No Morbidity	Morbid	Major Morbidity	
	Number of cases (percent dying within 30 days)				
Pneumonia or COPD	214 (38.3)	2,327 (5.5)	655 (13.4)	356 (43.8)	3,552 (12.8)
Coronary revascularization	102 (31.4)	1,837 (2.5)	988 (3.8)	440 (18.0)	3,367 (5.8)
Acute myocardial infarction	412 (72.8)	1,386 (6.4)	1,044 (12.8)	470 (56.2)	3,312 (23.8)
Congestive heart failure	249 (34.1)	1,735 (6.8)	1,127 (12.8)	413 (43.3)	3,524 (14.9)
Cholecystectomy	202 (0.0)	2,581 (1.2)	632 (3.6)	174 (14.4)	3,589 (2.2)
Prostate surgery	228 (0.0)	3,217 (0.8)	165 (4.8)	31 (19.4)	3,641 (1.1)

TABLE 3—Variation in Probability of Death within 30 Days of Admission Explained (R-Squared) by Admission Score Alone, by Mid-Stay Score Alone, and by Admission Plus Mid-Stay Score, by Condition

Condition	Admission Score Alone	Mid-Stay Score Alone	Admission Plus Mid-Stay Score
Pneumonia or COPD	0.11	0.15	0.24
Coronary revascularization	0.04	0.08	0.16
Acute myocardial infarction	0.16	0.34	0.41
Congestive heart failure	0.06	0.12	0.18
Cholecystectomy	0.01	0.04	0.05
Prostate surgery	0.01	0.03	0.05

with the surgical conditions having lower death rates (1.1–5.8 percent) than the medical conditions (12.8–23.8 percent), (Table 1). The distribution of cases across admission severity scores also varied by condition. For example, only 6.1 percent of the surgical cases had high admission scores of 3 or 4, compared with 30.4 percent of the medical cases. Within all six conditions, higher admission scores were generally associated with higher death rates.

However, even among cases with identical admission scores, those in conditions with higher overall death rates generally had higher severity-score-specific death rates. For example, among the six conditions, prostate surgery cases had the lowest overall death rate (1.1 percent) while acute myocardial infarction cases had the highest (23.8 percent). Not only did prostatectomy contain far fewer cases with scores of 3 and 4 than did acute myocardial infarction (1.6 percent of cases compared with 33.2 percent), but also, within each of the five admission scores, the rate of dying was less than one-fifth as great for prostatectomy cases as for infarction cases.

The rates of death by mid-stay review score also varied widely across conditions (Table 2), as did the distribution of cases across mid-stay scores. Even with major morbidity, patients in the three surgical conditions were much less likely to die than their medical counterparts. Death rates rose somewhat between no morbidity and morbid, but the rates increased at least threefold between morbid and major morbidity.

Except in cholecystectomy and prostate surgery cases, many of the patients with no mid-stay review died. For instance, 72.8 percent of acute myocardial infarction patients without a mid-stay review died, as did 31.4 percent of coronary revascularization patients. Thus, the reason for the absence of a mid-stay review was often the early death of the patient. Nevertheless, most of the patients who died remained alive long enough to have a mid-stay review. In three conditions, the plurality of patients who died had major morbidity. In cholecystectomy and prostate surgery patients, the 1 percent death rate among the many cases with no morbidity represented more deaths than the over 14 percent death rates among the few cases with major morbidity. In contrast, 33.6 percent of acute myocardial infarction deaths occurred among patients with major morbidity, while 38.1 percent of deaths occurred among patients with no midstay review.

Explaining Variations in Rates of Death

When admission scores were used to predict 30-day mortality (Table 3), the R-squared values ranged from 0.01 in cholecystectomy and prostate surgery cases to 0.16 in acute myocardial infarction cases. In comparison, the mid-stay review score was a more powerful predictor of risk of death, with R-squared values ranging from a low of 0.03 for prostate surgery to a high of 0.34 for acute myocardial infarction. Combining information about the admission and mid-stay scores generally yielded much greater predictive power than did either score alone, producing the highest R-squared value in all conditions.

Given the large fraction of deaths among those without a mid-stay review, we looked at whether the fact of a mid-stay review alone was predictive of death. We regressed 30-day mortality on a dichotomous variable indicating the presence or absence of a mid-stay review. For acute myocardial infarction cases, the R-squared value produced was 0.19. For other conditions, however, the R-squared value was much smaller: 0.04 for pneumonia/COPD and coronary revascularization, 0.02 for congestive heart failure, and 0.00 for cholecystectomy and prostate surgery. Thus, in all conditions, the simple fact of a mid-stay review did not appear to cause the greater predictive power of the mid-stay review categories.

Discussion

The superior performance of the two approaches involving the mid-stay review was not primarily related to the fact that the absence of a mid-stay review identified patients who died quickly, except among acute myocardial infarction patients. Probably more important is the reliance of the mid-stay review score on physiological derangements generally one week into the hospitalization. It seems almost a clinical truism that patients with severe problems this far into the admission would have worse prognoses than patients without such findings. By contrast, however, admission scores include severe physiological derangements that can often be treated effectively with current medical therapeutics. This conjecture is consistent with the relatively weak performance of the admission MedisGroups score as a predictor of mortality.

In general, patients in the three surgical conditions were much less likely to die, despite high admission scores. The reason may be that those acute physiological derangements that present on admission (and are reflected in high admission scores) represent manifestations of the patients' underlying disease, which will be explicitly addressed by the surgery, usually with a successful outcome (especially for cholecystectomy and prostate surgery). In contrast, certain physiological derangements stemming from acute and chronic medical ailments may be less amenable to control and resolution.

This study has several limitations. First, the number of deaths was relatively small, especially for the surgical conditions. Thus, the R-squared values reported here (particularly for the combined admission and mid-stay score model) may be inflated by overfitting. Second, the results cannot be generalized to younger patients, although the case selection strategy included a small number of Medicare beneficiaries younger than 65 years of age. Finally, MedisGroups was developed to reflect events during a hospitalization. By focusing on death within 30 days of admission, we included some events that occurred following discharge. When analyses were repeated using in-hospital death, admission scores and mid-stay scores produced R-squared values virtually identical to those for 30-day mortality, except for acute myocardial infarction cases, for which the R-squared value for the mid-stay score was 0.39 for in-hospital death compared with 0.34 for 30-day mortality. Similarly, for the combination of admission and mid-stay scores the R-squared values were only 0.01 to 0.03 higher for predictions of in-hospital mortality, except in acute myocardial infarction cases, for which the R-squared value was 0.47 for in-hospital death compared with 0.41 for 30-day mortality.

Even if the mid-stay review score were perfectly predictive of mortality, it is not at all clear that it would be an appropriate risk adjuster for widespread quality assessment efforts, such as the federal hospital-level mortality figures. The mid-stay review rating could be affected by shortfalls in the quality of care, the very event that mortality statistics seek to identify. Therefore, adjusting mortality figures by the mid-stay review score could mask instances of quality problems.

For such risk adjustment, the appropriate construct is the admission "severity" score, which performs relatively poorly as a predictor of 30-day mortality in this data base. These findings could be contrasted with those produced by other models of admission severity, such as the Medicare Mortality Predictor System[14,15] and the Acute Physiology and Chronic Health Evaluation,[16-18] but such comparisons would be hampered by differences in the data bases, predictive models, and statistical techniques used in the different studies. No published research yet exists comparing the performance of various severity systems as predictors of 30-day mortality on comparable data bases across conditions.

Although these results must be viewed as preliminary and pertinent only to Medicare beneficiaries, they may have important implications for states and regions that have mandated the collection of severity information for assessing hospital quality, especially if one purpose is to examine severity-adjusted mortality rates. For example, Pennsylvania and Iowa now require hospitals to collect patient severity information using MedisGroups, with one goal being to examine severity-adjusted outcomes. Our findings raise the crucial question: What causes the large amount of variation in death rates unexplained by the MedisGroups admission score? Further study is needed to answer this question so that the MedisGroups information can be used in an appropriate and valid fashion. □

Acknowledgments

We are grateful to Henry Krakauer, MD, PhD, Health Standards and Quality Bureau, Health Care Financing Administration, for furnishing the data base and assisting us in its use. We also thank Elizabeth Estabrook, RN, and Paul Steen, MD, of MediQual Systems, Inc., for their assistance and comments. APPENDIX—Description of MedisGroups

Selection of Key Clinical Findings

Assignment of MedisGroups severity scores derives from the number, type, and weights of the Key Clinical Findings (KCFs) identified for each individual case. More than 250 potential KCFs are considered, using patient history; physical examination; and laboratory, radiology, pathology, and procedure results to indicate clinical abnormalities. All KCFs are used in computing admission scores, but only a subset of KCFs is involved in deriving the mid-stay review score.

The admission review aims to reflect both acute clinical derangements and more chronic conditions. It encompasses the first two calendar days of the hospital stay for medical patients. For surgical patients, the timing of the admission review depends on when the operation takes place. The intent is to capture all aspects of the surgery, including pathological findings, as part of the admission review. The worst values obtained during this period are collected to compute the admission score.

The so-called "mid-stay review" aims to identify acute or subacute "morbidity" following the admission period. Although all KCFs are collected and all physiological derangements are considered, the mid-stay review computation disregards most chronic or prolonged manifestations of disease. For example, abnormal arterial blood gases in a patient with COPD are included, whereas the chest radiograph finding of COPD would be excluded. The MedisGroups algorithm classes the KCFs used for this mid-stay rating as "acute" (e.g., hematocrit, glucose, blood pressure, pulse, coma, and ventricular fibrillation on electrocardiogram) or "persistent" (e.g., ascites on ultrasound, extensive burns, congestive heart failure on chest radiograph, disorientation, and pulmonary embolism on arteriography).

For most medical cases, the mid-stay review encompasses days 3 through 7 of the hospital stay. For most surgical cases, this review covers the five days following surgery. The worst values obtained during the mid-stay period are collected, but information on vital signs and 10 laboratory KCFs must come from the last 48 hours of the period. Patients generally do not receive a mid-stay review if discharged alive during the designated period.

Scoring

Individual KCFs are assigned weights or "groups" from 0 to 3; group 3 findings indicate a serious clinical derangement and imminent risk of organ failure. Examples of group 0 KCFs include history of congestive heart failure, heart murmur on physical examination, colonic polyp on colonoscopy, serum sodium greater than 128 mmol/L, systolic blood pressure greater than or equal to 60 mmHg, and spinal cord compression found on computed tomography. There are very few group 3 findings; they include coma or stupor on neurological examination, arrest with resuscitation, burns covering greater than 25 percent of body surface area, hematocrit less than 20.0 percent, and systolic blood pressure less than 60 mmHg. Although computation of scores disregards patient age, special pediatric ranges are specified for selected continuous KCFs, and a number of KCFs apply only to neonates.

Employing the algorithm shown in Table A, admission severity scores from 0 to 4 are computed based on the KCFs identified and their weights (i.e., group assignments from 0 to 3), regardless of diagnosis. Using the designated "acute" and "persistent" KCFs, the mid-stay review score is also computed independently of diagnosis, and it results in three classes: no morbidity, morbid, and major morbidity (Table B).

TABLE A—Meaning and Computation of Admission Scores

Score	Meaning of Score	Computation of Score
0	No significant findings	All other, such as cases with multiple group 0 KCFs
1	Minimal findings, indicating a low potential for organ failure	One or two group 1 KCFs
2	Either acute findings connoting a short time course with an unclear potential for organ failure, or severe findings with high potential for future organ failure	One group 2 KCF *or* Three or more group 1 KCFs
3	Both acute and severe findings indicating a high potential for imminent organ failure	One group 3 KCF *or* Two or more group 2 KCFs
4	Critical findings indicating the presence of organ failure	Two or more group 3 KCFs

TABLE B—Meaning and Computation of Mid-Stay Score

Mid-Stay Score	Computation of Mid-Stay Score
No morbidity	All other
Morbid	One group 2 acute KCF *or* One or more group 2 persistent KCFs
Major morbidity	One or more group 3 acute KCF *or* More than one group 2 acute KCF *or* One or more group 2 acute KCF *and* one or more group 2 persistent KCF

The Impact of HIV-Related Illness on Employment

ABSTRACT

We used structured telephone interviews to determine the extent of work loss following onset of symptoms, the interval between onset of symptoms and cessation of work, and the risk factors for work loss among 193 persons with symptoms of human immunodeficiency virus (HIV)-related illness attending the AIDS Clinic at the University of California, San Francisco, between October 1, 1988, and September 30, 1989. Estimates of the duration of time between onset of HIV-related symptoms and work loss derive from the life table method of Kaplan and Meier. A Cox proportional hazards model is used to estimate the effect of risk factors on the probability of withdrawing from work in each time interval. Eighty-six percent of the respondents worked prior to onset of the first symptom of HIV-related illness; 40 percent were working at the time of the most recent interview, a mean of 958 days later. The total number of hours worked declined by 59 percent during this time. Kaplan-Meier analysis indicates that 50 percent who worked prior to onset of HIV-related illness stopped working within two years and all had stopped within 10 years after onset of the first symptom. (*Am J Public Health* 1991; 81:79–84)

Introduction

The economic cost of acquired immunodeficiency syndrome (AIDS) has been the subject of numerous studies.[1-28] Several analysts have noted that the largest component of the cost of human immunodeficiency virus (HIV)-related illness is due to lost work rather than to direct expenditures for medical care,[1-3] reflecting onset of this condition among persons in the first half of their careers. However, to date there have been no direct estimates of the magnitude of such work loss. For example, in the first comprehensive study of work loss due to HIV-related illness, Hardy, *et al*,[1] applied estimates from Rivin, *et al*,[4] to persons in their samples. Rivin, *et al*, in turn, relied on physicians' recall of their patients' work status in the three months prior to a telephone interview or, if the patients had previously died, in the three months prior to death. Scitovsky and Rice[2] assumed that any person alive at the end of a year was too ill to work 60 percent of the time and that anyone who had died during the year was unable to work at all in that year. The Rivin, *et al*, estimates depended on physicians collecting and remembering information about work status; the Scitovsky and Rice estimates depended on assumptions about the productivity of individuals with AIDS or AIDS-related complex (ARC), assumptions that they did not test directly.

The present study is designed to provide more direct information about the impact of HIV-related illness on loss of employment, clearly the largest component of the cost of these conditions.

Methods

We collected data from persons attending the AIDS Clinic at the University of California, San Francisco (UCSF), which provides medical care to persons with all stages of HIV-related disease. We use those data to quantify 1) the percentage of those employed prior to the first onset of symptoms with HIV-related illness and the percentage employed at the time of the most recent interview; 2) the change in the length of the workweek between the first onset of symptoms and the time of the most recent interview; and 3) the interval between the first onset of symptoms and the cessation of work activities. In addition, we describe the medical and demographic characteristics of persons with HIV-related illness as well as the characteristics of their jobs that are associated with the cessation of work.

Sampling

The sampling frame for this study consists of all 293 persons with HIV-related illness attending a randomly chosen session of the UCSF AIDS Clinic between October 1, 1988, and September 30, 1989. These 293 persons were offered enrollment in the clinic setting; completed telephone interviews eventually were conducted with 193 of them (66 percent). Study respondents are interviewed three times annually to provide an update on health status, medical care usage, and employment history. As of December 1989,

Kaposi's sarcoma	26	29
Pneumocystis carinii pneumonia	34	34

[a] Mean ± standard deviation.

97 respondents had been due for reinterview. Of these, nine had died, two refused continued participation because of illness, nine were lost to follow-up, and 77 were reinterviewed. Four persons who were reinterviewed subsequently died, as did one individual not yet due for reinterview.

Study Instruments

The principal data collection instrument is a structured, closed-ended telephone survey conducted by a trained interviewer who asks respondents to report whether they experience each of 20 common symptoms of HIV-related illness, (e.g., weight loss, fever, night sweats) and when the onset of each occurred; whether they experience each of 20 common medical conditions associated with HIV-related illness (e.g., Kaposi's sarcoma, *Pneumocystis carinii* pneumonia) and when the onset occurred; whether they have been told by a physician that they meet the standard criteria for AIDS or ARC, and when they were told so. The respondents provide a complete record of their current medications and those they have taken in the past for HIV-related illness. Following standard protocols for studies measuring labor force participation,[29] the respondents also provide an employment history for the time at which they noticed the first symptoms of HIV-related illness and at the time of the interview. In the employment history, respondents report whether they were employed, looking for work, out of the labor force, or disabled when they first noticed symptoms of HIV-related illness. If they were working, they report hours worked per week, occupation, and industry, and answers to a checklist of working conditions. They then provide the identical information for the day of the interview. Respondents who stopped working in the interim report the approximate date on which they left employment.

Data Analysis

The goal of the analysis is to describe the employment consequences of HIV-related illness among study respondents. We measure the impact of such illness in terms of actual work status—whether the individal is employed for pay in the labor market and, if so, the hours of employment. Thus, we do not measure the impact of HIV-related illness on those who have lost function but are not gainfully employed.

Estimates of the duration of time between onset of symptoms (or diagnoses) and cessation of work activities derive from the life table method developed by Kaplan and Meier,[30] with the censored cases being those who continued to work until the date of the most recent interview or who have been lost to follow-up. A Cox proportional hazards model[31] is used to estimate the effect of the respondents' demographic and medical characteristics, as well as of their job characteristics on their probability of withdrawing from work in each time interval.

The estimates of time to cessation of work activities reported here may be conservative. First, in attempting to renew contact with some of the respondents, we found that many have moved out of the area so that they could be cared for by parents or siblings and have, therefore, left work; such persons are recorded as being lost to follow-up. Second, of the 14 individuals who died subsequent to the first interview, 13 worked prior to onset of HIV-related symptoms. Of these, 6 stopped working by the last time we interviewed them. For the 7 others, for whom we could not establish the actual date on which work activities ceased, we arbitrarily assigned the date of data analysis (September 1, 1989) for the cessation of work activities. This strategy inflates the estimates of time between onset of symptoms and work loss.

Results

Table 1 shows the demographic characteristics of all study respondents and of those with a work history. Almost all are males, most are non-Hispanic Whites, and more than two-thirds finished college. Although a majority worked in white-collar occupations prior to the onset of HIV-related illness, sizable minorities were employed in service work or manual labor.

Table 2 summarizes the symptomatic history of the study respondents. Ninety-six percent reported having at least one potential symptom of HIV-related illness. On average, the symptomatic respondents experienced their first symptom 958 days prior to the most recent inteview, although the responses ranged from 0 days to more

TABLE 2—Symptomatic History of Study Respondents

Symptom	Percent with Symptom (n = 193)	Duration with Symptom, in Days (Mean, ± Standard Deviation, Range)
One or more symptoms of any kind[a]	96	958 ± 677, 0–3, 931
One or more neurological symptoms[b]	60	604 ± 521, 0–3, 931
One or more symptoms of dementia[c]	31	525 ± 336, 0–1, 353
One or more physically limiting symptoms[d]	45	831 ± 584, 0–3, 210

[a] Includes night sweats, diarrhea, shortness of breath, chronic cough, weakness, fatigue, confusion, memory loss, vomiting, pain, changes in sensation, loss of vision, skin lesions, oral thrush.

[b] Includes subset of confusion, memory loss, changes in sensation, loss of vision.

[c] Includes subset of confusion, memory loss.

[d] Includes subset of shortness of breath, weakness, fatigue, pain, loss of vision.

TABLE 3—Productivity of Study Respondents Prior to First Symptom and at Time of Most Recent Interview

All Workers	Full-time Workers	Part-time Workers
	Prior to First Symptom	
(*n* = 166, 100%)	(*n* = 146, 88%)	(*n* = 20, 12%)
	Hours/Week: Mean, Total, Percent

than 10 years. Sixty percent of the respondents reported one or more neurological symptoms lasting slightly more than 600 days on average; fewer than a third reported symptoms of dementia, and just slightly fewer than half reported a physically limiting symptom.

At the time of the first symptom of HIV-related illness, 166 respondents (86 percent), were working and 27 (14 percent), were not. This breakdown is very similar to the 84 percent labor force participation rate among all 35–44-year-olds in the United States.[32] At the time of the most recent interview, however, only 77 respondents (40 percent) were working. This figure represents a decrease of 54 percent in the labor force participation rate of the study respondents. Seventy-three persons, or only 44 percent of those who were employed prior to noticing the first symptom of HIV-related illness, were still working at the time of interview. In contrast, 93 individuals, or 56 percent of those employed prior to the first symptom, were no longer working.

Table 3 summarizes the productivity dynamics among the study respondents. The 166 persons who worked prior to the first symptom of HIV-related illness averaged slightly more than 38 hours a week, or 6,381 hours total; 88 percent of them were employed full time. The full-time workers accumulated 5,938 hours per week, or 93 percent of all hours worked. The 77 persons who were working at the time of the most recent interview averaged 34 hours work per week. Their total work time, 2,616 hours, represents a decrease of 59 percent in productivity, with a much larger share of the total hours being accumulated by part-time workers. In fact, the number of part-time workers increased absolutely (from 20 to 26) and relatively (from 12 percent to 34 percent), as did the number and relative share of part-time hours (from 443 [7 percent] prior to the first symptom to 555 [21 percent] at time of interview).

Table 4 apportions the productivity gains and losses of the study respondents by their work histories over the average of 958 days between the first notice of symptoms and the most recent interview. Four respondents began working after the onset of the first symptom of HIV-related illness and another three increased their hours. Forty-nine persons (29 percent of respondents) did not change their hours at all between first onset of a symptom and the most recent interview. Slightly more than 12 percent continued to work, but with reduced hours. Those who stopped working altogether constitute the largest group of respondents (55 percent), and their lost productivity, 3,510 hours, accounts for 90 percent of the overall reduction in hours.

Figure 1 presents Kaplan-Meier estimates of the time to cessation of employment among persons working at the first notice of symptoms. Among all study respondents who had one or more symptoms and who worked prior to the onset of HIV-related illness, 10 percent had stopped working within 100 days of their first symptom (95 percent CI-5, 15). Within a year, 28 percent had stopped working (95 percent CI-21, 36); by two years, 48 percent had done so (95 percent CI-40, 56); by four years, 69 percent had left work (95 percent CI-59, 79); and by 10 years, none was still employed. Among persons who would ultimately develop neurological symptoms, 30 percent had stopped working prior to doing so; among those remaining, 19 percent had stopped working in the first days after onset of neurological symptoms (95 percent CI-10, 28). No respondent with neurological symptoms has been followed for longer than 1,886 days, by which point the 84 percent who were employed when they developed the first neurological symptoms had stopped working (95 percent-CI 58–100).

Figure 2 provides estimates of the time between specific HIV-related diagnoses and the cessation of work activities. Fourteen percent of persons with AIDS had stopped working prior to receipt of that diagnosis. Thereafter, 10 percent had stopped working in the first days after diagnosis (95 percent-CI 3–16), 40 percent had stopped working within a year (95 percent-CI 29–51), and 93 percent were no longer employed as of 1,986 days after diagnosis (95 percent-CI 80–100), the longest any respondent with AIDS has been followed. Of those with ARC, 40 percent had stopped working prior to formally receiving that diagnosis. Thereafter, the proportion working fell steadily, but at an initially slower rate than that of persons diagnosed with AIDS. Ultimately, however, the proportion of working persons with ARC reached zero. Work loss oc-

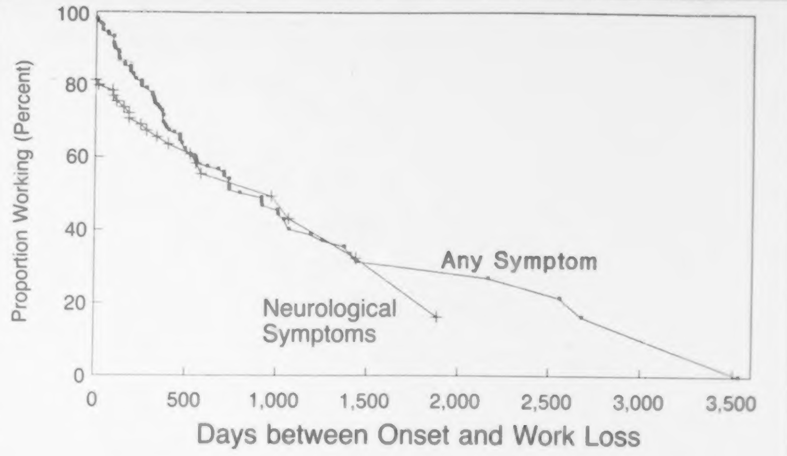

FIGURE 1—Time between Onset of Symptoms and Work Loss

curred more slowly for persons classified as asymptomatic, with 30 percent leaving work by 1,003 days (95 percent-CI 1–59), the longest any respondent formally so classified has been followed.

In a separate analysis, we compared the time between diagnosis of AIDS and cessation of work for persons with Kaposi's sarcoma and those with other conditions that result in the AIDS diagnosis (not shown in Figure 2). This comparison yielded only equivocal evidence that persons with Kaposi's sarcoma are likelier to leave work in each time interval than those with other AIDS-related diagnoses (p = .24 by Wilcoxin test).

In Table 5, we present estimates of the proportional hazard of work loss associated with characteristics of the respondents and of the jobs they held at the time they first noticed symptoms of HIV-related illness. A proportional hazard less (greater) than 1.0 indicates that the person with the risk factor is less (more) likely to stop working in each time interval after onset. Persons with a diagnosis of AIDS stopped working at much higher rates than those who were diagnosed with ARC or who were asymptomatic. Age, a history of male homosexuality or intravenous (IV) drug use, union status, and job tenure did not affect work status. Members of minorities were slightly, though not significantly, more likely to stop working than non-Hispanic whites. The nature of work at the job held at the first onset of symptoms, however, did affect subsequent work status. The proportional hazard of work loss associated with an increment of *each* of the 11 physical requirements of the job was 1.09, indicating that persons with very physically demanding work would have much higher rates of work loss than those in sedentary occupations. Conversely, the proportional hazard of work loss associated with an increment of *each* of the nine measures of discretion in work activities was .93, indicating that persons who controlled the pace and scheduling of work activities were much less likely to leave employment.

Discussion

Both the individuals with HIV-related illness and the society of which they are a part have a strong interest in sustaining the employement of these individuals for as long as possible. Doing so brings such benefits as the sense of well-being they get from continuing in work despite illness, the relatively high income they generate from employment (an average of $30,000 a year prior to the onset of HIV-related illness among the study respondents), and the taxes they pay. The cessation of work on the other hand, initiates one series of entitlements and hastens the day when others will begin. Most persons with HIV-related illness who leave work will apply for unemployment insurance immediately. Those with a diagnosis of AIDS will be eligible for Supplemental Security Income (SSI) as well. If such persons had private disability policies through work, they may begin to collect on them. For those who did not have health insurance through a former em-

[a] *p*-value by chi-square test.

[b] Count of physical requirements of jobs, including walking, using stairs, standing or sitting for long periods, stooping, reaching, using eyes for reading or inspection, concentrating or memorizing, using computers, using fingers to grasp, lifting 25 lbs.

[c] Count of discretion over work activities, including pace of work, work procedures, what is produced, time of breaks, sick leave, time of arrival and departure.

ployer, most will be granted Medicaid; those who *did* have health insurance through work, can retain it—at their own expense—only for a year and a half, and then they too will apply for Medicaid. Finally, if they survive the waiting period, they may collect Social Security Disability Insurance (SSDI) and, subsequently, most of those receiving SSDI will become entitled to Medicare.

These potential consequences of work loss following onset of HIV-related illness have been noted before, and there is evidence that the growth in entitlement that follows the cessation of employment has already begun.[4,5,10,18-21,25,26]

There are other compelling reasons as well for understanding the impact of HIV-related illness on employment. As these illnesses become more like other chronic conditions, interventions that maintain function will begin to take precedence over those that merely prolong survival, especially at the cost of function.[33]

There are few data with which to estimate the magnitude of work loss related to HIV-related illness, however. Although the current study is designed to provide direct estimates of such work loss, limitations in the study design may limit the generalizability of these estimates. The study population, although apparently reflective of persons with HIV-related illness in the San Francisco Bay Area,[4,5,34] probably includes a disproportionate number of male homosexuals and persons with a work history compared with the national population of persons with HIV-related illness. Sampling within a clinic setting may also bias the estimates, although after using procedures designed to correct for this problem through weighting,[35-36] we could not detect such a bias and, accordingly, reported the unweighted results above. Finally, the results may be sensitive to the nonparticipation rate.

We found that among all persons with at least one symptom of HIV-related illness, half had stopped working within two years of onset and all had stopped within a decade. Most of the lost productivity is due to total cessation of work rather than to reduced hours. Given that the average age of the study respondents is only 38, most will lose well over half of their careers.

As one might expect, persons who have received a diagnosis of AIDS were at higher risk to stop working in each interval between the first onset of symptoms and the most recent interview than those who have been diagnosed with ARC or who are classified as asymptomatic. Contrary to expectation, risk status—history of male homosexuality or IV drug use—was not associated with work status. Persons who reported that the job they held when they first noticed symptoms of HIV-related illness required more physical exertion and those who reported less discretion over the pace and scheduling of work activities were likelier to withdraw from work in each interval between onset and interview, a finding consistent with studies of work loss after onset of rheumatoid arthritis,[37-38] all forms of musculoskeletal disease,[39] and chronic disease generally.[40] This finding suggests that one way to forestall work loss would be to refer persons with HIV-related illness to less physically demanding work and to jobs in which the employee has discretion over the pace and scheduling of tasks. However, given that the work disability rate eventually reaches unity, any such attempt will have but a temporary effect.

The data reported here reflect the current therapy available at a tertiary care center over the past several years. Advances in treatment could dampen the rate at which work loss occurs among persons with HIV-related illness and, in doing so, prove highly cost-effective. A change in attitudes among employers might alter the willingness of afflicted persons to persevere in the face of illness. The addition of long-term care to the typical workplace-based health insurance policy might remove the incentive to leave work to obtain long-term-care services. In advance of such changes, we find that work loss after onset of HIV-related illness is a pervasive phenomenon. ☐

Reporting of Occupational Injury and Illness in the Semiconductor Manufacturing Industry

ABSTRACT

In the United States, occupational illness and injury cases meeting specific reporting criteria are recorded on company Occupational Safety and Health Administration (OSHA) 200 logs; case description data are submitted to participating state agencies for coding and entry in the national Supplementary Data System (SDS). We evaluated completeness of reporting (the percentage of reportable cases that were recorded in the company OSHA 200 log) in the semiconductor manufacturing industry by reviewing company health clinic records for 1984 of 10 manufacturing sites of member companies of a national semiconductor manufacturing industry trade association. Of 416 randomly selected work-related cases, 101 met OSHA reporting criteria. Reporting completeness was 60 percent and was lowest for occupational illnesses (44 percent). Case-description data from 150 reported cases were submitted twice to state coding personnel to evaluate coding reliability. Reliability was high (kappa 0.82–0.93) for "nature," "affected body part," "source," and "type" variables. Coding for the SDS appears reliable; reporting completeness may be improved by use of a stepwise approach by company personnel responsible for reporting decisions. (*Am J Public Health* 1991; 81:85–89)

Stephen A. McCurdy, MD, MPH, Marc B. Schenker, MD, MPH, and Steven J. Samuels, PhD

Introduction

Occupational injuries and illnesses represent an important health and economic cost in the United States. The US Department of Labor recorded more than six million cases of reportable occupational injuries and illnesses in 1987, including more than 50 million lost work days.[1] Health and economic consequences for individual workers due to occupational disorders range from trivial to devastating.

Epidemiologic study of occupational disorders has been hindered by the lack of a comprehensive reporting system providing reliable and consistent statistics.[2] The Occupational Safety and Health Act of 1970 attempted to address this problem by mandating the nationwide collection and analysis of statistics on occupational illnesses and injuries meeting specified reporting criteria.[3] The act defines an occupational injury as a disorder that results from an instantaneous exposure (e.g., an impact or fall) occurring in the work environment. Disorders resulting from work exposures that are not instantaneous are considered illnesses. Reporting is mandatory for all cases of occupationally related deaths, all occupational illnesses, and those occupational injuries meeting at least one of four reporting criteria; 1) injuries requiring medical treatment other than first aid, 2) restriction of work or motion, 3) termination or transfer to another job due to the injury, and 4) loss of consciousness.[3]

Each reportable case (and associated lost or restricted work days) is recorded in the company Occupational Safety and Health Administraiton (OSHA) 200 log and classified as an injury or one of the following seven categories of occupational illness: skin diseases, dust diseases of the lungs, toxic respiratory conditions, systemic poisonings, disorders due to physical agents, disorders due to repetitive trauma, and other occupational illnesses. A sample of approximately 280,000 establishments is selected annually to forward a summary of information from the OSHA 200 log to the Bureau of Labor Statistics (BLS) for analysis and subsequent publication.[4] Additional information, including job title and description of the incident and resultant disorder, is recorded on an OSHA 101 form or equivalent state worker's compensation insurance form, which constitutes the Supplementary Data System (SDS). Coding for the SDS is performed by participating state agencies; in California the responsible agency is the California Department of Industrial Relations (CDIR).

In spite of the importance of these data, little research has been conducted to assess the completeness or reliability of reporting for OSHA-reportable conditions. We report here the results of an investigation of reporting of illness and injury in accordance with OSHA reporting criteria among members of the Semiconductor Industry Association (SIA). In addition, two samples of SDS forms were submitted to the CDIR to evaluate the reliability of coding decisions.

Methods

Population

The SIA is a national trade association of semiconductor manufacturing firms (Standard Industrial Classification code 3674). In 1982, the SIA sponsored the development of the Occupational Health System (OHS), a prospective computerized data collection system operating in parallel with the governmental OSHA 200 reporting system. Sixteen companies comprising 37 plant sites and employing more than 96,000 workers, or approximately one-third of semiconductor manufacturing employees in the US in 1984,[4] participated in the OHS. All manufacturing sites participating in the OHS in 1984 agreed to participate in an evaluation of their recording practices.

Company Health Record Review

We evaluated the reporting completeness and reliability of case description data for 1984. Review of cases from the company clinic daily log was conducted at a sample of sites chosen on the basis of a stratified sampling scheme. The 10 sites contributing the most OSHA-reportable cases (median reported cases, 175; median number of employees, 5,951) and a random sample of six of the remaining 27 sites (median reported cases, 24; median number of employees, 920) were selected for site visits.

We examined the daily clinic log for 1984 and selected four work-related cases per month at random from each site. Only cases that the employer had previously determined to be work-related were sampled. When it was available, the abstracter also reviewed the OSHA 101 form (or equivalent state form for the workers' compensation employer's first report), the form for the physician's first report, and the case's personal employee health clinic chart.

If the exposure or event causing the employee's disorder was considered by the abstracter to be instantaneous, the case was classified as an injury. All lacerations, contusions, sprains, strains, and thermal burns were presumed to represent injuries unless the records explicitly indicated that the exposure causing the disorder was not instantaneous. Cases that were likely to have resulted from exposures that were not instantaneous were classified as illnesses. Examples include contact dermatitis due to gloves or creams, acid burns on the hand discovered after the removal of a faulty protective glove, and disorders due to repetitive trauma. Cases in which it could not be determined whether the exposure causing the disorder was instantaneous (e.g., "acid burn on hand") were classified as indeterminate.

We defined the reportability of cases according to BLS guidelines applicable in 1984.[3] The reportability for indeterminate cases was decided according to criteria for occupational injuries. Reporting criteria for injuries and indeterminate cases and work-related death were assumed to be absent unless specifically noted otherwise in the records.

The OSHA 200 form was reviewed to determine if the reportable cases had been recorded. Reporting completeness was calculated as the percentage of cases meeting OSHA reporting criteria that was recorded in the company's OSHA 200 log.

Reliability of SDS Classification

We received 1,117 OSHA 101 or equivalent state workers' compensation forms from a random 50 percent sample of OSHA 200 cases from 1984, as reported previously.[5] Of these, a random sample of 150 forms was submitted to the CDIR without data on the nature, type, source, and body part involved that could identify the person or the company. The initial classifications were stored and the forms were resubmitted without identifying data for repeat classification. The CDIR nosologists received the materials in batches and were not aware that some of the forms had been previously classified. Reliability was calculated as the kappa statistic.[6] Statistical analysis was conducted on a VAX 11/750 computer using the Statistical Analysis System (SAS) software package.[7]

Results

Sixteen sites, representing 66,968 employees, were selected for review. Six sites were not included because they did not have daily clinic logs or supporting records for 1984 suitable for participation in this study, leaving 10 sites representing plants in six states distributed across the US. These 10 sites consisted of seven from the stratum of 10 large case contributors and three from the stratum of six facilities representing the remaining sites.

We reviewed 416 randomly selected work-related cases from the clinic logs. Personal employee health charts were available in 249 (60 percent) of these cases. These records were not available in the remaining cases because of the inability of the companies to locate the records because of loss, transfer, or termination of the employee. There were 101 cases (24 percent) that met reportability criteria for the OSHA 200 form. The median number of reportable cases per site was 8.5 (range: 0–29).

Of the 101 reportable cases, 57 (56 percent) were injuries, 28 (28 percent) were indeterminate cases that met the reporting criteria for injuries, and 16 (16 percent) were occupational illnesses (Table 1). Fourteen (88 percent) of the occupational illness cases represented skin conditions, and the remainder were due to cumulative trauma. Sixty-one (60 percent) of the 101 reportable cases were recorded on the company OSHA 200 form. The completeness of reporting ranged from 13 percent to 100 percent at the nine participating sites with reportable cases. No as-

TABLE 2—Reliability of Classification for 150 Reportable Cases of Occupational Injury or Illness

Classification Variable	Kappa
Nature of injury or illness	0.92
Strain, sprain	0.95
Cut, laceration, puncture	1.00
Chemical burn	0.87
Contusions, crushing injuries, bruise	0.96
Affected body part	0.93
Back	1.00
Finger(s)	0.97
Eye(s)	0.96
Hand (not wrist or fingers)	0.92
Source of injury or illness	0.83
Boxes, crates, cartons, cases	0.97
Hydrofluoric acid	0.96
Bodily motion	0.75
Floor	0.79
Type of injury or illness	0.82
Overexertion in lifting object	0.93
Contact with radiation, caustics, etc. (by skin absorption)	0.94
Fall onto walkway or working surface	0.78
Bodily reaction	0.75

sociation was observed between employee population size or the number of reportable cases at a site and reporting completeness. Because reporting completeness was similar in the two sample strata, the strata were combined for analysis.

Of the 61 reportable cases recorded on the OSHA 200 form, 32 (52 percent) were classified by the abstracter as recordable injuries, 22 (36 percent) were classified as recordable indeterminate cases, and 7 (11 percent) were classified as occupational illnesses (Table 1). Of the 7 illness cases that were reported, 5 (71 percent) were misclassified as occupational injuries. Three of these cases were occupational skin diseases and two were illnesses due to repeated trauma.

For the combined 85 cases of reportable injuries or reportable indeterminate cases, 55 (65 percent) were reportable because of the use of medical therapy beyond first aid and 33 (39 percent) were reportable because of restriction of work motion. Reporting completeness was 78 percent for restriction of work motion cases and 56 percent for medical therapy cases. Reporting completeness was lowest for illnesses. No cases of loss of consciousness or termination or transfer due to an injury and no occupational deaths were observed.

Of the 40 reportable cases that were not recorded on company OSHA 200 logs, 25 (63 percent) were classified by the abstracter as reportable injuries, 9 (23 percent) were occupational illnesses, and 6 (15 percent) were reportable indeterminate cases. The most common reportability criteria among the injury and indeterminate cases were use of medical therapy other than first aid (24 cases) and restriction of work or motion (8 cases). All of the 9 unreported occupational illnesses represented skin disease cases.

Reliability of SDS Classification

The reliability of classification by the CDIR was calculated as the kappa statistic and varied from .82 for type of condition to .93 for affected body part (Table 2). There was little variation in the kappa values between categories within nature, part, type, and source variables.

Discussion

Occupational morbidity imposes an important health and economic burden on individual workers, employers, and society. Primary prevention plays an important role in minimizing this burden. Preventive measures, although generally more cost-effective than treatment, require directed use of resources, and accurate epidemiologic information is needed to guide the application of these resources. The BLS report of occupational injuries and illnesses offers the only nationwide statistics for occupational injuries and illnesses based on standardized reporting criteria. We report the results of our evaluation of reporting completeness within a large and important industry and the reliability of coding for case description data by a state agency participating in the SDS.

A major goal of this study was to evaluate the reporting completeness for conditions that the employer considered work related. Cases that were not recognized as work related would not have been included in the study. True occupational cases may be missed if the employee does not seek medical attention or if the treatment practitioner or employer does not recognize the occupational relationship. Failure to recognize an occupational etiology is particularly likely for illnesses due to chronic exposures and characterized by subtle manifestations or long latencies, such as cancer, neurologic disease, and reproductive disorders. Lack of severity, incomplete medical evaluation, and inadequate recording practices may also lead to underreporting.

In the early 1980s OSHA implemented a site-inspection policy that focused inspections away from establishments that reported low injury rates, raising concern that this policy may promote underreporting. However, examination of these factors and estimation of the true rate of occupational injury and illness would have required active surveillance to capture true cases that would otherwise be undetected and were beyond the scope of this study.

Our findings suggest that the BLS data significantly underestimate incidence of occupational injuries and illnesses. If the 60 percent reporting completeness we observed for conditions recognized by the employer as work related is representative of other industries, the incidence may be nearly 70 percent higher than reported. The underestimation is most significant for occupational illnesses, for which the 44 percent reporting completeness we observed suggests that the incidence may be almost 130 percent higher than reported. The true incidence of occupational conditions is likely to be significantly higher, because the estimates calculated above are based upon observed reporting of conditions recognized by the employer as work related.

Among injury and indeterminate cases, the highest reporting completeness occurred for cases characterized by restriction of work or motion. Injuries and indeterminate cases characterized by the need for medical treatment were less likely to be recognized as reportable. Thus, BLS data are likely to be most valid for conditions such as injuries that directly affect the ability of a worker to perform a job.

The results of this investigation may have been affected by selection bias. The companies studied are members of a large trade association and may not be representative of this industrial sector with respect to reporting performance. Companies not belonging to the trade association may have fewer resources to devote to surveillance and prevention of occupational conditions. Thus, reporting completeness in the group we studied may be higher than for nonmembers. Because the firms participating in this study represent a large fraction of this important industrial sector, we do not believe that any selection bias would have seriously altered our findings and conclusions.

Information bias may also have affected our observed results. Personal employee health charts to supplement data contained in the clinic log were not available for approximately 40 percent of the 416 cases selected for review. Although the clinic logs were generally the most helpful sources of information, personal employee health charts could have contained information indicating a reportable condition. By not reviewing all of these, we may have overestimated reporting completeness. Reporting completeness for occupational illnesses may have been overestimated because indeterminate cases were considered reportable only if they met reporting criteria for injuries. In other words, some indeterminate cases not meeting reporting criteria for injuries may have actually been illness cases but would not have been recognized and classified as reportable in this study. In addition, we presumed that reporting criteria were absent unless they were specifically noted as present; incomplete or incorrect medical record entries could have contributed to erroneous classification with respect to reportability.

Although the influence of these potential biases is difficult to quantify, the data indicate that significant underreporting for occupational disorders, especially illnesses, occurred in the semiconductor manufacturing industry. The increased underreporting for occupational illnesses is significant because the semiconductor manufacturing industry is chemically intensive,[8,9] and illnesses represent a greater proportion of OSHA-reportable cases in this industry than in the manufacturing sector in general.[10] Although the absence of a control industry in this investigation limits comparison with other industries, underreporting has been documented in recent studies of other industries. Eisenberg and McDonald[11] observed an underreporting rate of approximately 20 percent in a pilot investigation of OSHA-reporting practices in 192 manufacturing establishments in Massachusetts and Missouri.

Other investigations have attempted to assess the true rates of occupational conditions. For occupational deaths, estimates of underreporting from 30 to 50 percent have been reported.[12,13] A recent investigation by Blanc and coworkers[14] evaluated the usefulness of occupational illness surveillance using Poison Control Center data. These investigators suggested that the true incidence of occupational illness is three to five times current estimates. Thus, significant underreporting is likely to occur in other manufacturing industries, and a review of underlying causes and possible remedies discussed here may be valuable for industry groups not represented in this investigation.

We also observed misclassification of occupational illnesses as injuries. This phenomenon illustrates important inconsistencies in the OSHA 200 reporting system. Specifically, all occupational illnesses must be reported under the system, regardless of severity, whereas occupational injuries are reported only if they meet specific criteria reflecting severity. Furthermore, classification of illness or injury depends on the exposure leading to the condition. If the exposure was "instantaneous" (a time period defined only by examples of a fall or blow in BLS reporting guidelines), the condition is viewed as an injury. Conditions resulting from all other (i.e., noninstantaneous) exposures are considered illnesses.

Thus, classification of injury and illness in the OSHA system is based on duration of exposure instead of on a biological index such as the nature or severity of the medical condition. Persons unfamiliar with this classification system might use a more biologic and intuitive approach and classify certain illnesses, such as repetitive trauma disorders or chemical burns, as injuries. In addition, the duration of exposure may not be precisely known, and reporting completenes will depend on the interpretation of incomplete or equivocal exposure information by the companies' reporting personnel. However, the majority of underreported or misclassified cases reported here were not equivocal; underreporting appeared due to inconsistent use of published reporting criteria addressing the clinical features of the case.

In spite of the limitations of this study, we have made several valuable observations on which to base specific recommendations. The OSHA data require company personnel at each facility to make case evaluation and classification decisions. Within an industry, the large number of facilities contributing cases introduces the potential of variable reporting practices between facilities, contributing to variability in the quality of the data. In contrast, the coding of clinical data entering the SDS is performed by a small number of trained personnel in a central state office. Our findings indicate that this practice is associated with high reliability of coding for clinical data. It would be impractical to submit all work-related cases to a central office for determination of reportability, and this responsibility is likely to remain at the level of designated personnel at each facility. Reporting practices may be improved and made more uniform by focusing educational measures on these personnel. Education should emphasize recognition of occupational illnesses, for which underreporting was most significant in this study.

We recommend that recording personnel use a formal, stepwise process that forces response to the following pertinent questions to determine reportability of occupational conditions.

- Was the exposure instantaneous (e.g., a fall or a blow)? All cases for which the exposure was not instantaneous are reportable as occupational illnesses. Cases for which the exposure was instantaneous are injuries; the following additional questions must be addressed to evaluate their reportability.
- Was medical treatment other than first aid required, as defined in BLS reporting guidelines?
- Was restriction of work or motion involved that interfered with normal work activities?
- Was there loss of consciousness?
- Was the employee transferred or terminated due to the condition?

If the answer to any of the last four questions is affirmative, the injury is reportable. Regular review of selected cases would help assure consistency and validity of results.

We also recommend that studies evaluating reporting practices be conducted in other industrial sectors. These studies would expand the findings of the investigation reported here and provide a more broadly based picture of the accuracy of national occupational injury and illness data based on the OSHA 200 log. Studies focused on specific occupational conditions should also be undertaken to evaluate the completeness and accuracy of reporting for the OSHA 200 system using independent data sources, such as cancer registries, workers' compensation records, hospital discharge data bases,[15] Poison Control Centers,[14] and occupational health clinics.[16] Accurate surveillance methodology is especially important for occupational illnesses, which are poorly captured by the OSHA 200 system.[13] Finally, case reportability criteria, currently constrained by the Occupational Safety and Health Act, should be reviewed and revised to conform to biological criteria rather than to duration of exposure. □

Acknowledgments

This study was supported by the Semiconductor Industry Association. We thank the person-

nel of participating companies for their cooperation and the personnel of the California Department of Industrial Relations for their coding of OSHA 101 forms or their equivalents.

NLM Collection of Posters for Public Health Issues

"Posters are the most ephemeral of objects. Designed to attract attention and to communicate their message rapidly, their aim is to persuade, sell, convince, or change behavior patterns . . . . With rare exceptions, their life is brief indeed.

"Yet many posters are worth keeping, either for their artistic qualities or for their timeliness as evidence of commercial or social attitudes . . . . Posters for tuberculosis, smallpox, and venereal disease published in the first half of this century now provide evidence of campaigns that met with varying degrees of success; at the same time they reveal approaches used by artists and designers in past years to achieve their desired aims."

So reads the narrative in a new catalog from the National Library of Medicine, describing "TO YOUR HEALTH: An Exhibition of Posters for Contemporary Public Health Issues."

Recognizing the valuable message contained in posters, the National Library of Medicine began a project in late 1987 to gather such posters for current public health campaigns from countries all over the world, with emphasis on the key public health matters of our times, such as smoking, substance abuse, AIDS, and sexually transmitted diseases. The project now has more than 2,500 posters in the collection and researchers are beginning to study them for clues to questions on current attitudes on health.

A current exhibition of 76 posters—now touring the nation—covers the following topics: breast-feeding, family planning, immunization, dental hygiene, coping with daily life, nursing, meetings and lectures, research, blood donation, smoking, substance abuse, alcoholism, venereal disease, and AIDS. To obtain a copy of the catalog of the exhibition, write: Chief, History of Medicine Division, NLM, 8600 Rockville Pike, Bethesda, MD 20894.

Trends in the Content and Use of Oral Contraceptives in the United States, 1964–88

B. Burt Gerstman, DVM, MPH, PhD, Thomas P. Gross, MD, MPH, Dianne L. Kennedy, MPH, Ridgely C. Bennett, MD, MPH, Dianne K. Tomita, MPH, and Bruce V. Stadel, MD, MPH

ABSTRACT

Drug marketing and physician survey data were used to examine trends in the use and hormonal content of oral contraceptives in the United States between 1964 and 1988. Retail prescriptions for oral contraceptives peaked at approximately 68 million in 1973 and have remained between 50 million and 60 million since 1981. Despite this relative consistency in the number of prescriptions, physician "mentions" of oral contraceptives have increased by approximately 75 percent. This increase may reflect closer monitoring of women on oral contraceptives. Use of multiphasic formulations has steadily risen, accounting for 37 percent of the oral contraceptive prescriptions in 1988. Mean estrogen and progestin doses in all types of formulations have steadily declined. A change in the type of estrogen and progestin used in preparations has coincided with this decline in dose. The association between age and use of high-dose formulations seen in the past was no longer evident in 1988. The data demonstrate that oral contraceptive formulations in wide use today differ in hormone content from those of the past, when most of the major studies addressing the risks associated with oral contraceptive use were completed. There is therefore a need to determine the risks and long-term effects associated with these newer formulations. (*Am J Public Health* 1991; 81:90–98)

Introduction

Since oral contraceptives were introduced three decades ago, 56 brands representing 33 unique formulations have been marketed in the United States (see Appendix). Most of these preparations have contained a constant amount of estrogen and progestin (*monophasic* combinations); other types are *sequential*, progestin only ("*minipills*"), and *multiphasic* formulations.

Sequential formulations contained estrogen alone during the first 14 to 16 days of use each cycle followed by an estrogen-progestin combination during the last five to seven days of use. These pills are no longer marketed but were available from 1965 to 1976. Minipills were first introduced in 1972 and have never accounted for more than a fraction of a percent of retail oral contraceptive prescriptions. Multiphasic formulations contain varying estrogen and/or progestin amounts during the cycle and were first introduced in 1982 in an attempt to emulate hormone fluctuations of the menstrual cycle and to lower overall hormone doses.

In considering the beneficial and adverse effects associated with specific oral contraceptive formulations, one must consider the types and doses of estrogen and progestin they contain. Two types of estrogen and nine synthetic progestins have been used in oral contraceptives. The two estrogens, ethinyl estradiol and mestranol, have identical biological effects. Some studies, mostly animal, suggest that on a weight-by-weight basis, ethinyl estradiol is more potent than mestranol in suppressing ovulation, since mestranol must first be converted in the body to ethinyl estradiol.[1–3] In the human body, however, differences in potency between ethinyl estradiol and mestranol do not appear to be important.[4] Progestins contained in oral contraceptives differ by orders of magnitude in potency and may demonstrate varying degrees of andro-genic, estrogenic, antiestrogenic, and other metabolic effects.[5–7]

This paper reports changes in the use of oral contraceptive formulations in the United States from 1964 to 1988. It also examines the relationship between formulation type and the age of users in the period 1980–88. An understanding of these trends is important to better interpret results of previous studies and to plan future studies that seek to clarify the relationship between oral contraceptive use and its potential to cause adverse as well as beneficial effects.

Methods

Sources of Data

Data from two pharmaceutical marketing research data bases produced by IMS America, Ltd. (Plymouth Meeting, PA), were used to examine trends in oral contraceptive use and prescribing. The National Prescription Audit (NPA) was used to provide information on the number or oral contraceptive prescriptions

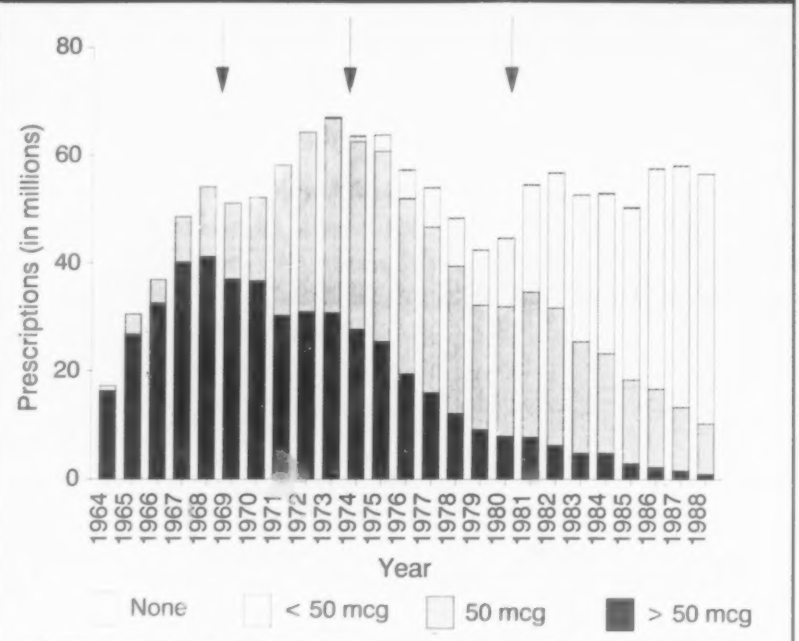

FIGURE 1—Number of Retail Oral Contraceptive Prescriptions by Estrogen Dose, 1964–1988, United States

Arrows indicate points at which changes in data collection methods occurred.

dispensed by retail pharmacies in the contiguous United States. Age-related trends in utilization were based on the National Disease and Therapeutic Index (NDTI) for the years 1980, 1984, and 1988.

The NPA derives its information from chain and independently owned retail pharmacies in the contiguous United States. Other dispensing outlets such as mail order pharmacies, supermarket pharmacies, and clinics are not included. IMS America estimates that retail pharmacies fill approximately 90 percent of prescriptions in the United States. This proportion, however, may not apply to oral contraceptive prescriptions, because approximately one in four women who use reversible forms of contraception rely on publicly funded clinics for care.[8] We were therefore unable to estimate the percentage of oral contraceptive prescriptions that is covered by this study. Nonetheless, previous studies have suggested that trends in oral contraceptive use reported by NPA accurately reflect trends in the general population.[9,10]

From 1981 to 1987, IMS audited all new and refilled prescriptions dispensed at 1,200 computerized pharmacies. This sample was expanded to 2,500 sites in 1987. From 1974 to 1980, data were derived from a representative sample of 800 pharmacies, each of which was audited for two days per month. From 1970 to 1974, 400 pharmacies were audited for four days per month. Prior to 1970, 200 pharmacies reported every fifth prescription filled during the first and third week of each month. Although these changes in methodology may create artifacts at points of change, trends within intervals are unaffected.

Information on the NPA sampling frame is updated annually. Sampled pharmacies represent the universe of retail pharmacies in terms of ownership type, size, and geographic region. Using sampling fractions based on these factors, the number of retail prescriptions dispensed nationwide was estimated.

The NDTI, used to provide information on physician usage patterns of oral contraceptives in relation to age of patients, is based on a sample of 2,130 physicians per quarter recruited from the membership rolls of the American Medical Association and the American Osteopathic Association. The NDTI sample is selected from four geographic regions and 19 specialties, and it is estimated that its sampling universe includes the prescribing practices of 270,827 office-based physicians, but not the prescribing of 51,112 other clinic- and hospital-based physicians. Projection factors derived from the number of physician-days for each of the defined geographic and specialty strata are used to project national estimates.

NDTI-audited physicians are asked to report on each private patient seen or contacted by phone during a specified 48-hour period. Physicians provide information on patient demographics, diagnoses, and treatments for each diagnosis rendered. By convention, the term "mention" is used to denote each drug considered or given during a patient contact. Drugs that are mentioned during a physician-patient contact may reach the patient through prescription, hospital order, provision of samples, or administration or dispensing in the office. It is worthwhile to note that mention of a drug does not necessarily mean that a prescription was issued. Projection factors derived from the number of physician-days in the sample relative to that of the universe for each of the geographically and specialty-defined strata are used to estimate national usage patterns.

Classification of Oral Contraceptives

Formulations were classified by type (monophasic, multiphasic, sequential, minipill), estrogen dose, estrogen contained (mestranol, ethinyl estradiol, none), progestin dose, and progestin contained. Progestins were grouped as follows: norethindrone, ethynodiol diacetate and norethindrone acetate (norethindrone derivative), norethynodrel (oral contraceptives containing norethynodrel were no longer marketed for contraception after October 1988) norgestrel, levonorgestrel, and progestins no longer used in current oral contraceptive formulations (dimethisterone, chlormadinone, medroxyprogesterone acetate). Norethindrone, ethynodiol diacetate, and norethindrone acetate were grouped because previous studies have suggested that these progestins demonstrate similar biological activity and are equally potent on a weight-by-weight basis.[11] We evaluated dose trends by examining both the percentages of retail prescriptions that contained more than 50 µg, 50 µg, and less than 50 µg of estrogen and the mean estrogen and progestin doses of oral contraceptive.

Results

As depicted in Figure 1, total prescriptions rose between 1964 and 1968. After a small decline in 1969, the annual number of prescriptions increased, peaking in 1973. From 1974 to 1979, the number of prescriptions declined steadily. The

1976	1.14	0.46	3.77	—	47	76
1980	1.01	0.41	3.92	—	41	66
1984	0.97	0.37	3.27	0.15	37	62
1988	0.89	0.35	2.73	0.11	35	57

[a] There were only two formulations containing ethinyl estradiol in 1964 (Norlestrin 2.5 mg and Provest), each of which contained 50 μg ethinyl estradiol.

SOURCE: National Prescription Audit, IMS America, Ltd., Plymouth Meeting, PA.

apparent increase in the number of dispensed prescriptions that is seen between 1980 and 1981 could be an artifact of a change in data collection methods that coincided with these dates. Since 1981, the number of prescriptions has remained between 51 million and 58 million.

Prescriptions demonstrate a distinct trend toward use of formulations that contain less than 50 μg of estrogen per tablet (Figure 1). In 1968, fewer than 1 percent of the estimated 54 million retail prescriptions for oral contraceptives were for formulations containing less than 50 μg of estrogen, whereas in 1988 approximately 82 percent of the approximately 57 million retail prescriptions were for formulations with less than 50 μg of estrogen. Retail prescriptions for sequential formulations (no longer marketed) reached their maximum in 1968 (Figure 2). The number of prescriptions for multiphasic formulations steadily increased after they were introduced in 1982, accounting for 37 percent of all retail oral contraceptive prescriptions in 1988.

Mean estrogen and progestin doses have declined over time (Table 1). Since 1981, ethinyl estradiol has become the most common estrogen (Figure 3). Oral contraceptives containing norethindrone derivatives increased market share during the 1960s and have remained fairly constant; they have been included in approximately 65 percent of prescriptions since 1970 (Figure 4). The recent increase in levonorgestrel from less than 1 percent of the market in 1982 to 19 percent in 1988 is attributable to the increased use of two triphasic preparations containing this form of progestin. At the same time, the use of norgestrel declined from 32 percent of the market in 1983 to 16 percent of the market in 1988.

Oral contraceptive mentions by office-based physicians have increased from 1980 to 1988 by 75 percent (13,501 × 10^3 mentions in 1988; 7,716 × 10^3 mentions in 1980: Table 2). The proportion of within-year mentions in the 15- to 24-year-old group has decreased relative to that of the 25- to 34-year-old group. In 1980, 15- to 24-year-old women accounted for 57 percent of oral contraceptive mentions and 25- to 34-year-old women accounted for 37 percent of mentions. In 1988, these figures were 48 percent and 45 percent, respectively. Mentions in the 35- to 44-year-old group accounted for 6 to 7 percent of mentions during this interval.

Mentions for multiphasic formulations increased between 1984 and 1988 (Table 2). In 1984, 15 percent of mentions were for multiphasic formulations. In 1988, 40 percent of mentions were for multiphasics. The largest use of multiphasics occurred in the 15- to 24-year-old age group.

The mean estrogen dose of mentions was directly associated with age of users in 1980 and 1984 (Table 3). The association between age and ethinyl estradiol dose was no longer evident in 1988; the average ethinyl estradiol dose in mentions was 35 μg, irrespective of age. The association between age and mestranol dose has weakened. In 1988, the mean mestranol dose for 15- to 24-year-old women was 56 μg, for 25- to 34-year-old women it was 54 μg, and for 35- to 44-year-old women it was 63 μg.

In 1980 and 1984, 35- to 44-year-old oral contraceptive users were more likely to use mestranol-containing formulations than their younger counterparts. By 1988, only 8 percent of mentions in 35- to 44-year-old women were for mestranol-containing formulations. This figure compares with 15 percent in 25- to 34-year-old women, and 6 percent in 15- to 24-year-old women.

Discussion

Data presented in this paper pertain to office-based physicians and exclude public clinics as a source of oral contraceptives. In addition, NPA data reflect the number of dispensed retail prescriptions but do not contain information on the number of cycles covered by each prescription. Therefore, NPA data cannot be used to estimate the prevalence of oral contraceptive use in the population. An additional limitation is that there has been no adjustment for change in the number of women of childbearing potential in the population. Despite these limitations, NPA and NDTI data are useful for monitoring large changes in the use of various oral contraceptive formulations over time.

Retail prescription data suggest that overall use of oral contraceptives has been fairly stable since 1981. NPA projections suggest a modest 2.4 percent increase from 1982 to 1987, compared with an 18.5 percent increase in the prevalence of oral contraceptive use reported by Forrest and Fordyce.[12] (Forrest and Fordyce report the percent distribution of women using oral contraceptives increased from 27 percent in 1982 to 32 percent in 1987.) However, neither of these estimates allows for sampling variation, and if we were to estimate the percent change in NPA from 1983 to 1987, a 10.3 percent increase would be noted. This inference, of course, is based on the assumption that both estimates are representative and unbiased and that the average duration of NPA prescription has remained constant over the time interval. However, direct comparisons between NPA projections and those offered by Forrest and Fordyce may not be justifiable, because the former refer to the number of retail prescriptions and the latter are based on self-reported use. Thus, these data are not fully comparable.

Although the number of dispensed retail prescriptions has been relatively stable, the number of NDTI mentions has increased by 75 percent. This apparent inconsistency may be the result of changes in survey methodology, or survey inaccuracy, or it may reflect a change in physician care of patients taking oral contraceptives. We speculate that the observed increase in mentions with no large increase in the number of dispensed prescriptions could be indicative of closer monitoring of women on oral contraceptives.[13]

The impact of the steady increase in the use of multiphasic formulations is unclear because the risks and benefits associated with them compared with other low-dose formulations are largely unknown. Although one article reported a series of functional ovarian cysts in women using multiphasic oral contraceptives,[14] previous studies have demonstrated a reduction in the incidence of

functional ovarian cysts in women using high- and intermediate-dose formulations.[15,16] No study to date has measured the risk of functional ovarian cyst formation in users of multiphasic formulations relative to nonusers or to women using other low-dose formulations. Gaspard and Lepot have reported no significant difference in follicular development between users of a low-dose monophasic formulation and its triphasic analog.[17]

Progestin doses have been declining over time. However, all progestins are not equipotent on a milligram-per-milligram basis. For example, previous studies suggest that norgestrel is 5 to 10 times as potent as norethindrone, and levonorgestrel is 10 to 20 times as potent as norethindrone.[10] Using these factors to adjust mean dose, today's norgestrel and levonorgestrel doses are comparable, in terms of potency, to norethindrone doses of the 1960s and 1970s (Table 1). In addition, norgestrel and levonorgestrel may demonstrate more androgenic activity than norethindrone derivatives.[18] Changes in oral contraceptive progestins may have effects on ratios of high- to low-density lipoproteins,[19] glucose tolerance, blood pressure,[20] and the risks of vascular disease,[21–23] benign breast disease,[24] and perhaps even breast cancer.[25]

A decline in the mean estrogen dose contained in formulations was observed. Because the intravascular coagulation and the activity of several clotting factors appear to be estrogen dose dependent,[26–28] this decline has probably resulted in a decline in the incidence of adverse cardiovascular events associated with oral contraceptive use.[29–31]

The correlation between age and high-dose estrogen oral contraceptives seen in the past[32] has almost disappeared. For the most part, women of older reproductive age who choose to use oral contraceptives have taken advantage of the risk reductions associated with low-dose estrogen formulations.

Our data confirm that the oral contraceptives of today contain less hormone than those of the past, when most of the major studies that addressed the risks associated with oral contraceptive uses were completed. Some of these previously defined risks may not necessarily be associated with today's formulations. Additional risks, if any, are not fully known. There is therefore a need to determine the acute and long-term effects associated with these newer formulations. ☐

The Status of Restrictive Smoking Policies: A Survey of Medical Schools in the United States and Canada

Frances A. Stillman, EdD, and Diane M. Becker, ScD, MPH

ABSTRACT

All schools of medicine in the United States (N = 128) and Canada (N = 16) were surveyed by telephone to determine if they had instituted policies to restrict smoking. Some policy restricting smoking was reported by 80.56 percent of US schools (N = 103) and by 93.8 percent of Canadian schools (N = 15). However, only 52.3 percent of US (N = 67) and 56.3 percent of Canadian medical schools (N = 9) indicated they had formal written policy statements. Only 13 percent of US schools and 19 percent of Canadian schools had banned smoking totally. (*Am J Public Health* 1991; 81:101–102)

Introduction

Systematic investigation of medical schools' smoking policies have not appeared in the public health literature on smoking policy implementation. This study was designed to determine the extent to which medical schools in the United States and Canada have responded to escalating efforts to eliminate smoking from health care training settings.[1-6]

Methods

Designated representatives from all 128 schools of medicine in the United States accredited by the Association of American Medical Colleges and all 16 schools of medicine in Canada with associative membership status[7] were interviewed by telephone by means of a standardized survey instrument. Surveys were directed to the deans' office and other administrative divisions responsible for regulating smoking for faculty, staff, and students. Data were obtained on reported smoking policies and the implementation process. Each institution that reported a definite smoking policy was asked to provide a copy of the written policy for review. Policy documents were reviewed independently by two raters to ascertain the content and level of restrictiveness of the policy. Interrater agreement was 100 percent.

The policies were classified as "common courtesy," designated no-smoking, designated smoking, total ban, or a total ban plus employee-student restrictions (i.e., on hiring practices, admitting smoking students to the medical school, or both).

A policy classified as common courtesy was one in which the prevailing trend was to seek the preference of others in the environment to determine if there were objections to smoking. Generally smoking would be discouraged only if complaints were raised.

A policy classified as designated no-smoking was one in which smoking was prohibited in designated areas (i.e., lecture halls, labs, and classrooms) but permitted in all other areas.

A policy classified as designated smoking prohibited smoking throughout the environment except in varying numbers of indoor designated areas.

A policy classified as a total ban was one in which smoking was prohibited in all of the interior environment; and no areas for smoking were provided.

A policy classified as a total ban plus employee-student restrictions consisted of a total ban on smoking and a decision not to admit students who smoked to the medical school or hire staff who smoked.

Results

The rate of response to the telephone survey was 100 percent. Based on self-reported survey data, 80.5 percent (N = 103) of US schools and 93.8 percent of Canadian schools (N = 15) indicated the presence of a smoking policy. The majority of schools reported policies of the designated no-smoking type.

Only 52 percent (N = 67) of US and 56 percent (N = 9) of Canadian medical schools that reported having a smoking policy acknowledged the existence of written policy documents. Only two US schools reported having the most restrictive type of policy, which both banned smoking and restricted hiring of employees and admittance of students to nonsmokers. Both schools did so based on religious reasons. The majority of US schools (83 percent) and Canadian schools (75 percent) prohibited the sale of cigarettes on their campuses.

Figure 1 summarizes the percentage of schools with a formal written policy statement grouped according to policy type. All schools in the US and Canada that reported having formal written policies sent copies of their written policy statements. Of the 21 percent of US

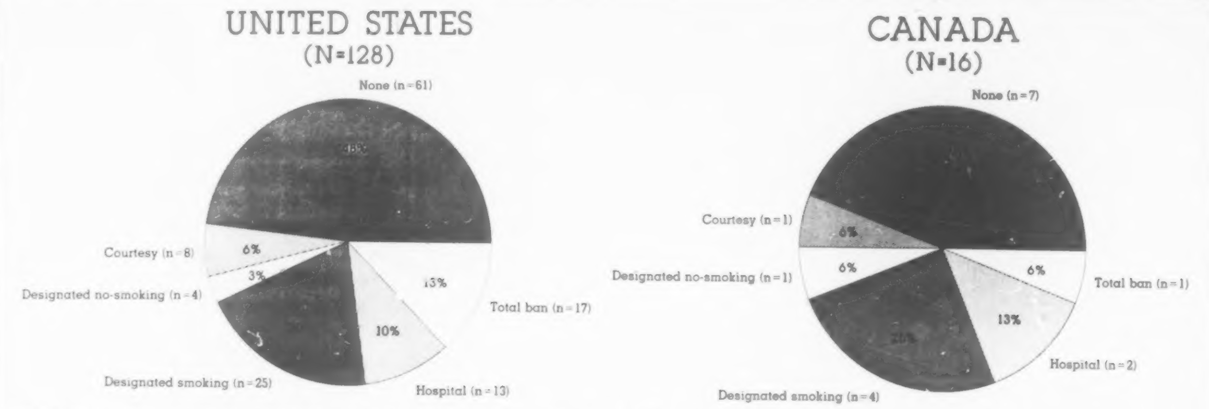

FIGURE 1—Percentage of medical schools with formal smoking policies, by type of policy

schools (N = 27) that reported the existence of a total ban, only 13 percent (N = 17) had formalized the ban into written format. The additional category of "hospital policy" denoted medical schools that had policies that affected only their associated hospitals but not their medical school environment.

Table 1 provides details about the distribution of medical schools with a smoking policy by region based on the written policy statements submitted. The eastern US and the Great Lakes region of Canada had the highest percentage of schools with policies.

While 52 percent of US schools reported providing smoking cessation assistance to students or staff before the policy was implemented, only 36 percent continued to provide some such assistance once restrictions were enforced. The type of assistance provided included formal on-site smoking cessation programs, self-help materials, health screenings, cash incentives for quitting, and referral to community-based smoking cessation programs. In Canada, 53 percent of medical schools provided assistance during the implementation phase of the no-smoking policy.

Discussion

Medical schools with formal policies totally banning or markedly restricting smoking remain in the minority. While the majority of medical schools reported the presence of some smoking policy, barely half of all schools had written policies. The finding that only a relatively low number of schools had made any formal commitment to smoking reduction is surprising given the escalating public interest in smoking and health and reports of successful smoke-free policy implementations in health-care settings.[8,9] By prohibiting smoking, medical schools can make a definitive health statement and act as models of healthy behavior. ☐

TABLE 1—Percentage of US and Canadian Medical Schools with Formal Written Smoking Policies, by Region

Measurement of Attitudes and Behaviors in Public Health Surveys

François Béland, PhD, Brigitte Maheux, MD, PhD, and Jean Lambert, PhD

ABSTRACT

We divided 900 general practitioners into two groups: one group received a questionnaire measuring both attitudes and behaviors toward preventive aspects of medical care, while the other received two separate questionnaires—one measuring behaviors, and one measuring attitudes. Response rates of the two groups were similar. Respondents in the first group retrieved their answer to the attitudinal items when responding to behavioral items, increasing the correlations between attitudes and behaviors by an average of .147 as compared to the second group; hence the second procedure was preferable. (*Am J Public Health* 1991; 81:103–105)

Introduction

Attitudes and behaviors are salient factors in most of the current public health issues. Most studies measure attitudes and behaviors using a set of items included in a single closed-form questionnaire. Inasmuch as attitudes and behaviors toward the same act are examined, the wording of the items and the response formats should be nearly identical to each other.[1–13] Feldman and Lynch[14] implied that a response to a question is likely to be retrieved as a basis for a subsequent response if they are presented consecutively in one questionnaire. Using similarly worded items to measure attitudes and behaviors compounds the problem. In the present paper we address the question of whether attitudes and behaviors can be measured accurately with a single questionnaire.

Methods

We randomly divided a sample of 900 general practitioners into two groups. One group (A) received a questionnaire in which both their attitudes and behaviors were assessed. The other group (B) received a questionnaire measuring behaviors; on receipt of that completed questionnaire, we mailed them a second one which pertained to their attitudes.

The response rate for group A was 64.3 percent. The response rate for group B was 73.2 percent. Ninety-two percent of the physicians in group B who answered the first questionnaire also completed the second questionnaire.

Twenty-one attitudinal items based on a series of questions (see Appendix) and 21 similarly worded behavioral items were presented to physicians on a six-point rating scale. They measured practices that physicians considered appropriate to perform (attitudes) and those which they claimed to perform (behaviors) in three clinical situations:

- the extent of information that a physician should provide to chronically ill patients about their illness;
- the extent to which a physician should promote non-smoking behavior to patients that consult for reasons other than smoking problems;
- the extent to which a physician should discuss weight with an obese patient consulting for reasons other than obesity.

The items measuring attitudes and behaviors were worded in the same manner.[14] Systematic biases in measuring attitudes and behaviors were assessed by comparing the correlation coefficients between attitudes and behaviors in the two groups of physicians.

The correlation coefficients were transformed into z-scores, using the Fisher Transformation, to test for the difference[15] between the association of attitudes and behaviors in the two groups of respondents. A total of 21 tests were performed for each of the comparisons between two groups. A P-plot procedure was used[16] to estimate the number N of true null hypotheses. The estimate of N was then used to obtain an overall α-level which was less conservative than the usual Bonferonni level. The value of N was 6 in this study, thus the significant level was set at $.05/6 = .008$.

Results

Eight correlations between attitudes and behaviors were different in the two groups at the 0.008 level (Table 1). Pearson's correlation coefficients between attitudes and behaviors were larger by an average of .147 in the group who received one questionnaire than in the group who answered two separate questionnaires.

Some differences in the item variances emerged (data not shown). Because a correlation coefficient is obtained from the division of the covariance with the variances, a small difference in variances can produce large differences in the estimated correlation coefficient. To test whether the differences in the correlations were due to differences in the variances in

the items, the 21 variance-covariance matrices for attitudinal and behavioral items of the two groups were compared using the Joreskög procedure.[17] Only four covariances out of 21 were significantly different between the two groups, while 14 variances were significantly different. As a consequence, the differences in the estimated variances had an effect on the estimate of the correlations.

Discussion

The results of our study showed that respondents to a questionnaire, wherein attitudinal items are followed by similarly worded behavioral items, retrieved their answer to the attitudinal items in order to answer questions on behavioral items. Pearsons correlations between attitudes and behaviors were larger by an average of .147 in the group who received one questionnaire than in the group who answered two separate questionnaires.

Some of the differences between the correlations were accounted for by the variances. Thus, fewer covariances than correlations were affected by the data collecting procedures. However, because there were significant differences in the means on the behavioral items between the two groups (table not shown) and because the computation of the covariances depends on the means, the estimates of the covariances were also biased.

Psychometric methods are used in attitudinal and behavioral scale testing. More often than not, researchers use a correlation matrix rather than a covariance matrix when testing for reliability and studying the validity of their scales. Thus, using one or two questionnaires would yield very different reliability coefficients.

The data from this study suggest that when similarly worded items are used to test for both attitudes and behaviors, two questionnaires are required. Nevertheless, the effect of features of questionnaire design should be tested before such a radical conclusion becomes conventional practice. For example, the set of behavioral items was listed immediately after the set of attitudinal items in this study. Had we introduced questions on other topics between the two sets of questions the response bias might have been lowered. Also, it may be possible to use different items to measure both or to use a set of similarly worded and a set of differently worded items. ☐

APPENDIX—The 21 Attitudinal Items

Items	Questions
Q1	**The general practitioner is often called upon to treat patients suffering from chronic pathologies. When a physician treats a patient suffering from high blood pressure, diabetes or arthritis, for example, should he inform him about:**
	ITEM 1 The medical name of the illness
	ITEM 2 The nature of the illness (e.g. chronicity, diseased organ)
	ITEM 3 The cause of the illness
	ITEM 4 The probable evolution of the illness, if treated
	ITEM 5 The name of the medication prescribed
	ITEM 6 The type of medication prescribed (e.g. diuretics, hypotensor)
	ITEM 7 The respective role of each medication
Q2	**Should the physician do the following things with the types of patients outlined above?**
	ITEM 8 Write a memorandum of the main items of information for the patient
	ITEM 9 Give the patient written documentation on his/her illness
	ITEM 10 Review with the patient at the next visit, the information he/she received from you previously
	ITEM 11 Give the patient the names of resources to contact for additional information on his/her illness (e.g. dietitian, association, etc.)
	ITEM 12 Inform the patient about the good popular books published on his/her health problem
Q3	**Finally, should the physician do the following things according to you?**
	ITEM 13 Try to find out about the patient's social environment
	ITEM 14 Inquire about the worries of the patient vis-à-vis his/her illness
	ITEM 15 Evaluate the support which the patient receives from those who are close to him/her
Q4	**Now let us consider another type of situation frequently encountered in practice. In the case where a young smoker consults for a particular problem unrelated to smoking, do you think the physician should do the following things?**
	ITEM 16 Obtain information on the smoking habits of the patient
	ITEM 17 Check if the patient knows the risks of smoking to his/her health
	ITEM 18 Encourage the patient to stop smoking
Q5	**Finally, in a case where a young obese person consults for a particular problem unrelated to obesity, do you think the physician should do the following things?**
	ITEM 19 Tell the patient what his/her ideal weight should be
	ITEM 20 Offer the patient your help if he/she decides to lose weight
	ITEM 21 Encourage him/her to lose weight

Determinants of Condom Use among French Heterosexuals with Multiple Partners

Jean-Paul Moatti, PhD, Nathalie Bajos, Jean-Pierre Durbec, PhD, Collette Menard, and Caroline Serrand

ABSTRACT

In September 1988, a sample of French individuals between 18 and 49 years of age, who reported more than one sexual partner in the past six months and who considered themselves heterosexuals (n = 1088), were interviewed at home about risk perception of human immunodeficiency virus (HIV) transmission, sexual behavior, and condom use. Systematic or occasional use of condoms during the previous 12 months was reported by 46.9 percent of respondents. Among condom users, 38.7 percent declared they had never used condoms before the last 12 months, fear of acquired immunodeficiency syndrome (AIDS) rather than contraception being the main motivation of these recent users. Multivariate analysis indicates that voluntary testing for HIV, average or more than average fear of sexually transmitted diseases (STDs), and knowledge of HIV carrier in personal relations are associated with condom use. (*Am J Public Health* 1991; 81:106–109)

Introduction

Since the beginning of the AIDS (acquired immunodeficiency syndrome) pandemic, designing effective prevention has been hindered by a lack of basic information about sexual behavior. While changes in sexual behavior and condom use among homosexual and bisexual men are becoming documented,[1–4] data are still very scarce for the general population.[5] The most recent data on sexual behavior in a large sample of the French population were obtained in a 1969 governmental survey.[6]

France has the highest number of AIDS cases in Europe: 8,025 reported between 1978 and September 30, 1989. A total of 2,176 new cases were diagnosed between October 1, 1988 and September 30, 1989 with 11.5 percent of these cases being due to heterosexual transmission. Although, in France as in the United States, heterosexually acquired AIDS remains focused in demographically distinct population groups (sexual partners of bisexual males, intravenous drug users and individuals of African or Carribean origin),[7,8] prevention of heterosexual HIV (human immunodeficiency virus) spread remains a challenge.

The objective of the present study was to investigate condom use and its determinants in a national sample of French heterosexual population whose sexual behaviors are at risk for HIV transmission. The survey was carried out at a national level in September 1988 and supported by the French Committee for Health Education which was officially in charge of public information campaigns about AIDS.

Methods

The survey data are based on respondents between 18 and 49 years of age, who reported more than one sexual partner in the six months prior to interview and who considered themselves heterosexuals. Individuals were contacted at home. After a short presentation, a written list of various statements corresponding to possible combinations of multiple sexual partners (such as "I am currently married but I had an extramarital sexual relationship during the past six months," etc.) was submitted to the respondents, and they were asked if they recognized having been in at least one of these situations during the past six months. All those who answered positively were included in the survey and were interviewed face to face. The questionnaire included detailed data collection about sociodemographic characteristics and 62 questions about perception of the risk of HIV transmission, sexual behavior, and condom use. The interview lasted between 45 minutes and one hour. Sex of interviewer and respondent were not matched.

A quota sampling procedure for age, sex, occupational status, and size of town was used to select the sample. These quotas were a priori defined on the basis of the observed characteristics of the subgroup of heterosexuals reporting more than one sexual partner during the past six months in a previous survey on AIDS of French general population (December 1987).[9,10] Among the total number of individuals who were contacted at home, 15.3 percent (n = 1,008) and whose characteristics are listed in Table 1 were included in the sample. About half (49.8 percent) were single and a third (34.1 percent) were university graduates.

Univariate statistical analyses and multiple logistic regression analysis were performed with condom use as the dependent variable.

TABLE 1—Frequency of Condom Use by Characteristics of the Respondents

Characteristics	% of Individuals Having Used Condoms during the Previous 12 Months
Sex	
Male (n = 501)	52.3
Female (n = 507)	41.6
Age (years)	
18–29 (n = 517)	50.7
30–39 (n = 325)	43.7
40–49 (n = 166)	41.6
Marital Status	
Single (n = 502)	52.6
Married or as married (n = 359)	41.2
Separated or widowed (n = 147)	41.5
Size of Town	
Less than 100,000 inhabitants (n = 432)	41.9
More than 100,000 inhabitants (n = 576)	50.7
Level of Education	
University graduates (n = 344)	51.7
College graduates (n = 222)	47.3
Lower level (n = 442)	43.0
Employment	
Executives, professionals and middle management (n = 351)	46.2
Employees and blue-collar workers (n = 423)	47.5
No occupation (n = 234)	47.0
Individual's Perception of Risk of Contracting AIDS	
Greater than average (n = 66)	53.0
Average (n = 235)	52.8
Less than average (n = 495)	46.3
None (n = 212)	40.1
Individual's fear of STDs	
Greater than average (n = 171)	55.0
Average (n = 475)	53.3
Less than average or none (n = 362)	34.8
Past Medical Care for STDs	
Yes (n = 215)	53.5
No (n = 793)	45.1
Testing for HIV	
Voluntary testing for HIV (n = 128)	71.9
HIV testing during systematic screening (n = 127) (blood donation)	44.4
No HIV testing but thought about having a test (n = 322)	47.8
No HIV testing and did not think previously about having one (n = 431)	39.7
Personal Knowledge of a HIV Carrier	
Yes (n = 153)	62.1
No (n = 855)	44.2

Results

Condom Use and Characteristics of Users

In this French sample, 46.9 percent reported having used condoms during the previous 12 months, 10.3 percent always using them. Among these 473 condom users, 38.7 percent declared they had never used condoms before the previous 12 months. These recent users mentioned fear of AIDS as their motivation for condom use in the same proportion as earlier condom users (65.0 percent vs 60.7 percent); however, they reported contraception as a motive for condom use less frequently (31.7 percent vs 62.8 percent).

Condom use is related to several sociodemographic characteristics of respondents as well as risk perception of contracting AIDS and STDs (sexually transmitted diseases) and past medical care for STDs (Table 1). It is of interest that 47.2 percent of respondents who feel being at "average" or "higher than average" risk of contracting AIDS do not yet use condoms (Table 1). Condom use is highest among respondents who voluntarily underwent testing for HIV antibodies and lowest in the non-tested population. It is also more frequent among respondents who personally know an HIV carrier (Table 1).

A minority of respondents (10.2 percent) believe that coïtus interruptus, vaginal douche, or to urinate after sexual intercourse may protect against HIV transmission; but their frequency of condom use is similar to that of the rest of the sample.

Determinants of Condom Use

When a logistic regression model is applied to condom use (either on some or all occasions of sexual intercourse in the last 12 months) and separate regressions are done by sex of respondents, the following variables appear to be related with use: voluntary testing for HIV, average or more than average fear of STDs and knowledge of HIV carrier in personal relations (Table 2).

Perception of Condom Use

Table 3 shows that expressed arguments about individual difficulties to use condoms such as "they are difficult to use" or "they reduce personal interest in sexual intercourse" do not differentiate users from non-users. It is rather criticisms of the social and cultural image of condoms with its potential effect on individual relationships that are more frequently expressed by non-users than users. Non-users also express more doubts about effectiveness of condoms to protect against transmission of HIV and other STDs.

Discussion

Several caveats must be recognized at the outset concerning our data. In the absence of sufficiently large and unbiased samples indicating the real prevalence of various sexual behaviors in the French population, our respondents cannot be considered as fully "representative" of French heterosexuals with multiple sexual partners. Inclusion in the study was based on individuals' willingness to recognize they had more than one sexual partner in the previous six months; so, reliability and validity of answers are difficult to assess (unfortunately, a possible influence of the interviewer's gender on the respondents' answers was not controlled). Our results are very similar to those observed in December 1987 in a representative sample of the population of 18 years of age and over of Paris region: in that survey of the general population, previous testing for HIV, being

TABLE 3—Expressed Opinions about Condoms

	Respondents		
% of Respondents Who Agree with the Following Statements about Condoms	Condom Users (%)	Condom Non-Users (%)	Difference (95% CI)
Are difficult to use	18.8	21.7	2.9 (−2.1, 7.9)
Reduce personal interest in sexual intercourse	60.7	64.2	3.5 (−2.5, 9.5)
Induce sexual impotence	5.5	6.2	0.7 (−2.2, 3.6)
Limit one's sexual pleasure	54.8	69.5	14.7 (8.8, 20.6)
Limit sexual pleasure of partners	59.6	62.4	2.8 (−3.2, 8.8)
Kill romanticism in relationship	62.6	76.8	14.2 (8.6, 19.8)
Create doubts about partner	28.1	40.0	11.9 (6.1, 17.7)
Are shameful to buy	7.2	12.3	5.1 (1.5, 8.7)
Should be considered like ordinary consumer goods	70.6	55.9	14.7 (8.8, 20.6)
Are not always effective STD protectors	55.2	66.4	11.2 (5.2, 17.2)

single, level of education, and declaring more than one sexual partner in the past six months were associated with condom use.[9,10]

Another limitation for our data is that those who report more than one sexual partner in the past six months may exhibit a wide variety of sexual behaviors to the risk of HIV transmission. Moreover, sexual-orientation self-reporting (i.e., heterosexual in our study) does not accurately describe an individual's sexual behavior: "heterosexuals," "bisexuals," and "homosexuals" may sexually interact across the boundaries implied by self-reported sexual-orientation.[11,12] Finally, condom use, especially if it is only occasional, is far from being a perfect indicator of protective behavior.

However, the aim of this study was to inform decision-makers in charge of public education campaigns about AIDS rather than to provide in-depth analysis of sexual behaviors. For that purpose, some useful indications and guidelines for general public information about condoms can be derived from our results.

Since 1987, French public health officials have tried to promote condom use through media advertising directed toward the general public (TV ads, newspapers, movies). It is well known that information alone does not cause sufficient change in behaviors, especially those which require significant changes in individuals' habits and self-representations.[13] It has even been argued that public education is particularly ineffective in areas or groups of low HIV prevalence.[14] Our study suggests a less pessimistic view: 18.2 percent of our sample being recent condom users of the last 12 months mainly motivated by fear of AIDS. It indicates that condom use has become relatively more acceptable in some segments of sexually active heterosexual population. Similar results have been found in The Netherlands where promotion of condom use in the general public also began in 1987.[15]

The experience of HIV prevention in the homosexual communities suggests that condom users are less likely than nonusers to believe that condoms "spoil sex" and that interventions should focus on helping people develop strategies and techniques that make condom use sexually satisfying.[16,17] From our results, it seems that other aspects must also be taken into account:

- The importance of fear of STDs as a predictor for condom use suggests that it may be useful to include information about condoms in the general context of STDs rather than to only associate them with prevention of HIV infection. Evaluation of various types of messages will be necessary to further document this point.
- Although expressed doubts about effectiveness of condoms among non-users may be an posteriori rationalization of behavior rather than a real barrier to use, it seems necessary to point out the effectiveness of condoms as a means of prevention and to popularize technical quality controls of the product.
- The most important aspect of general information about condoms may be to change their social image and to promote them as ordinary consumer goods playing a normal role in sexual and affective relationships. That is what French information campaigns have called a strategy for making condoms "more of a social routine." Some evidence observed among IV drug users seems to reach similar conclusions.[18]

French campaigns now issue messages about condoms which do not explicitly associate them with AIDS prevention per se and which emphasize their use as non-conflicting with socially and individually valuable relationships. ☐

Acknowledgments

This study was supported by the French Committee for Health Education (CFES) which is a governmental agency in charge of public health education campaigns.

Research on the Prevalence and Impact of Drug use in the Workplace: National Institute on Drug Abuse, Research Grants Program, Program Announcement No. PA-90-10, July 1990

The National Institute on Drug Abuse (NIDA) requests proposals from researchers in fields including but not limited to psychology, epidemiology, sociology, business and labor relations, public health, management, and economics, on the prevalence, etiology, and impact of acute, chronic, and "hangover" effects of drug use by the workforce. Specifically, NIDA requests proposals on:

- pacts of drug use on the workplace including absenteeism, accidents, injuries, job turnover, health care costs, and productivity effects;
- job performance assessment;
- simulation and field studies of workplace environments;
- prevalence and etiology of workplace-related drug use;
- prevalence estimation techniques for work-related populations; and
- studies of relationships among worker, job, and organizational characteristics, and patterns of drug use and consequences.

ADAMHA urges the inclusion of women and minorities in study populations. The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription Price is $80/year US; $120/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Cardiovascular Risk Factor Levels in Ethnic Hawaiians

ABSTRACT

We report a cardiovascular risk factor survey of "native" Hawaiians 20–59 years old (70 percent, or 257), living on the Hawaiian Homestead lands on the island of Molokai, Hawaii. More than 60 percent of both sexes were overweight. Among males, 42 percent were smokers. The percent of the population with systolic blood pressure greater than 140 mm Hg or a diastolic pressure greater than 90 mm Hg or taking hypertensive medications was 14 percent of those ages 20–39 and 36 percent of those ages 40–59. The percent with serum cholesterol ≥ 6.2 mmol/L ranged from 8 percent of those 20–29 years old to 46 percent in those 50–59 years old. Two percent of those ages 20–29 had a history of diabetes, or 2+ or greater glycosuria by dipstick, as did 23 percent of those ages 50–59. The majority of the known diabetics exhibited glycosuria and elevated glycohemoglobin levels, indicating poor control. Hypertension, although usually known to the participant, was frequently uncontrolled. From these data, it appears that among this group of Hawaiians major risk factors for cardiovascular disease were frequent, while at the same time the levels of awareness and/or control for most of these factors were low. (*Am J Public Health* 1991; 81:164–167)

Introduction

In the first years of contact with Westerners, the native Hawaiian population was devastated by epidemics of infectious diseases. Today the life expectancy of native Hawaiians remains the lowest of all the major ethnic groups in Hawaii.[1] The death rate from cardiovascular disease of "pure" Hawaiians is more than twice Hawaii's overall rate.[2] There are, however, few scientifically gathered data on risk factors for cardiovascular disease in native Hawaiians. This study was aimed at providing initial insight into the patterns of cardiovascular risk in a native Hawaiian population.

Methods

A cardiovascular disease risk factor survey of native Hawaiians living on Hawaiian Homestead lands on the largely rural island of Molokai, Hawaii, was conducted in 1985 with strong support from a Hawaiian advisory group. Hawaiian Homestead lands consist of tracts of land allocated by federal law for long-term lease, in individual parcels, to native Hawaiians with at least 50 percent native Hawaiian ancestry. The residents of these areas live primarily in extended family homes. The survey was carried out in conjunction with the INTERSALT project, an international cooperative study on sodium intake and blood pressure.[3] Some data collection instruments and training were common to the two protocols.

There are today relatively few genetically "pure" Hawaiians. Those who identify themselves as Hawaiians have many different lifestyles. Of the major Hawaiian islands, the island of Molokai has the highest proportion of its population who are Hawaiians or part Hawaiians. Because Molokai has experienced fewer of the lifestyle changes associated with mass tourism than other islands, its Hawaiian population, especially that portion living in the Homestead areas, is thought to be more typically Hawaiian. There is widespread unemployment and access to health care is limited.

A list of the individuals, by age and sex, known to be living in the Homestead areas was developed by interviewing longtime residents of the areas, examining hospital and clinic records and voter registration lists, and visiting most homes in the area. Introductory letters, brochures, and newspaper publicity as well as extensive telephone contact and visits to homes by staff and Hawaiian volunteers were used to recruit study participants. The population of individuals 20–59 years of age, excluding pregnant women, was defined as the target population. At the clinic appointment, health, lifestyle (smoking, alcohol use, and physical activity), and de-

Male	123	29	30	37	27
Female	134	27	46	35	26
Total	257	56	76	72	53

mographic questionnaires were administered. Nonfasting blood was drawn for cholesterol, triglyceride, high-density lipoprotein (HDL) cholesterol, and glycosylated hemoglobin measurements. Height, weight, and blood pressure were measured. Spot urine specimens were tested for protein and for glucose by means of dipsticks.

Blood specimens were refrigerated immediately and processed within four hours of collection. Serum specimens were frozen and transported frozen to the laboratory for analysis. Whole blood specimens were transported on ice for glycohemoglobin determinations, which were carried out within three to four days after collection.[4] Standardized Lipid Research Clinic procedures were utilized to determine serum lipid values.[5] Three sitting blood pressures were taken, after five minutes of rest, by individuals certified with the London School of Hygiene audiotape.[3] For each subject's blood pressure value in analyses, an average of the last two blood pressures was used. Hypertension was defined as either taking antihypertensive medications or having a diastolic blood pressure of 90 mm Hg or greater, or a systolic pressure of greater than 160 mm Hg.

Where appropriate, 95 percent confidence intervals (CIs) were calculated for total male and female rates based on the normal approximation to the binomial distribution.[6] These tended to be relatively wide because of the small sample size, and small numbers made the procedure inappropriate for the age-sex cells. Computer analyses of the 1976–80 National Health and Nutrition Examination Survey (NHANES II)[7] and the 1985 National Health Interview Survey (NHIS)[8] were conducted to provide comparative data on a national scale for comparable age groups.

Results

Tables 1 and 2 contain subject frequencies by age and sex and mean values and rates by sex for selected cardiovascular disease risk factors. Among the 367 persons identified as eligible, 257 (70 percent) participated in the study: 61 percent of the 20–29 age group, 72 percent of the 30–49, and 80 percent of the 50–59.

Approximately 65 percent of the participants were 20 percent or more above the average body mass index (weight-height ratio^2) for Caucasians, compared with 27 percent of all US adults ages 20–59.[9] Forty-five percent of the Hawaiians were 40 percent or more overweight by these standards.[9] The mean waist-hip ratio was higher than a 0.80 cut point,[10] indicating upper-body fat predominance, in all sex and age groups among the Hawaiians, but the finding was more marked in males.

Approximately 34 percent (95% CI = 26, 42) of females and 42 percent (95% CI = 32, 51) of males admitted to being current smokers by questionnaire. The highest prevalence of smoking was seen in males ages 20–29 (48 percent). Overall an additional 26 percent of males and 15 percent of females were past smokers.

The prevalence of high blood pressure or taking antihypertensive medications was 24 percent (95 percent CI = 19, 31) in females and 26 percent (95 percent CI = 19, 33) in males. The proportions are similar to those of Whites (Figure 1). Fewer than 7 percent of those meeting the criteria used for blood pressure elevations in these analyses had not been told previously that they had high blood pressure. However, among the 10 percent of the total population taking antihypertensive medications, 81 percent of females and 90 percent of males still had high blood pressures as defined.

The prevalence of individuals in the population with serum cholesterol of 5.2 mmol/L or higher was 50 percent for the males (95% CI = 41, 59) and 45 percent for the females (95% CI = 37, 53). The prevalence of those with serum cholesterol of 6.2 mmol/L or greater ranged from 9 percent in those ages 20 to 29, to 40 percent of those ages 50 to 59. The age-adjusted mean HDL was considerably lower

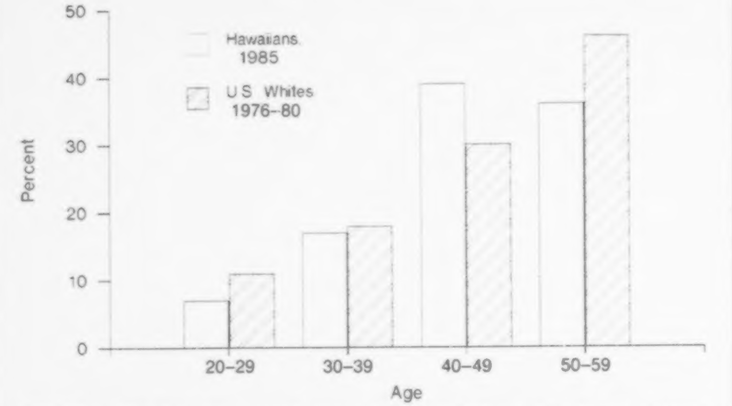

FIGURE 1—High Blood Pressure in Hawaiians vs. US Whites. Criteria of high blood pressure were diastolic blood pressure ≥ 90, or systolic blood pressure ≥ 140, or being on a regimen of antihypertensive medications. Data on US Whites are from the National Health and Nutrition Examination Survey, 1985.

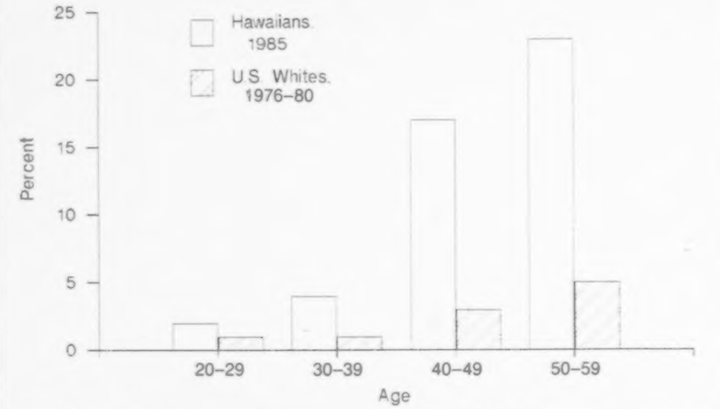

FIGURE 2—Diabetes in Hawaiians vs. US Whites. The percent of Hawaiians who said their doctors had told them they had diabetes or who showed significant glucose spillage (≥2+) in their urine at exam is compared with US Whites' rates of self-reported diabetes from the National Health and Nutrition Examination Survey, 1985.

among Hawaiian males (1.01 mmol/L [95% CI = 0.61, 1.55]) and especially in females (1.08 mmol/L [95% CI = 0.58, 1.58]) than values found for Whites of similar ages in the Lipid Research Clinics studies (males 1.16 mmol/L and females 1.49 mmol/L), indicating the possibility of substantially higher cardiovascular risk for Hawaiians.[11,12]

As shown in Figure 2, there was significant glycosuria (≥2+) in the spot urine or a history of the individuals being told they had an elevated blood sugar in 10 percent of females (95% CI = 5, 15) and 12 percent of males (95% CI = 6, 18). Among those 20–29, 30–39, 40–49, and 50–59 years of age, glycosylated hemoglobin levels greater than .11 were found in 2 percent, 7 percent, 8 percent, and 17 percent of these age groups, respectively, indicating an increased probability of glucose intolerance or poor control of diabetes.

Although there was no standardized follow-up, most of the six previously undiagnosed individuals with glycosuria are known to have been subsequently diagnosed by local physicians as having diabetes. The majority of the known diabetics were under poor control as evidenced by spillage of glucose in the urine and/or very high glycosylated hemoglobin levels.

Discussion

NHANES II found that 27 percent of US adults ages 20–59 were overweight,[9] compared with 65 percent of native Hawaiians in this survey, which used the same cut points for body mass index. The native Hawaiian males had more than twice the prevalence of overweight of US males in all age groups, whereas native Hawaiian females had 50 percent higher prevalence than US females. The predominantly upper-body type of fat distribution found in Hawaiians has been reported to be independently associated with higher risk of subsequent cardiovascular disease than is lower-body fat predominance.[10] However, ethnic differences in physiology and in the concept of ideal weight may contribute to the differences seen. Data from the 1985 NHIS indicate that 35 percent of US males and 31 percent of females in the age range 20 to 59 smoke.[7] The smoking rates among native Hawaiians appeared to be somewhat higher, and the age-specific patterns were most similar to US Blacks.

High rates of glucose intolerance have been found in some American Indian tribes.[13] Among urban Polynesians other than Hawaiians, rates of more than 12 percent for males and 11 percent for females have been reported, whereas rural rates are lower (1 to 4 percent).[14,15] In other Pacific populations, Micronesians from affluent, relatively westernized Nauru have a 30 percent prevalence of diabetes,[16] and Melanesian rates are low with rates in Fiji of 1.1 percent in the rural environment and 3.5 percent in an urban environment.[17] Many studies have implicated urbanization or westernization as a major risk factor for diabetes.[18]

The population studied was small, and previous experiences have made the Hawaiians suspicious of medical researchers; consequently overall response rates were held to 70 percent. For reasons of this kind, there are few population-based data on Hawaiians. In this study we had no indication that we were more or less successful in recruiting individuals with disease or elevated risk factors than healthier individuals, although the older individuals—who are more likely to have diagnosed disease and known risk factor elevations—were more likely to participate. As in any socioeconomically depressed population, out-migration is a problem and recruitment was somewhat more difficult in the young because of such factors as peer pressure, disillusionment, and work restrictions. As in any study, selective nonparticipation of healthy or ill individuals may have been possible. In order to better characterize the native Hawaiian population it is imperative that larger, better funded studies be carried out by working closely with native Hawaiians in multiple communities.

From these data, it appears that Hawaiians may be at high risk of premature coronary heart disease and stroke due to obesity, hypertension, hypercholesterolemia, low levels of HDL, smoking, and diabetes mellitus. In this population, individuals who were found to have significant abnormalities in the cardiovascular disease risk factors studied were often unaware of them, not under treatment, or not under adequate control. Such findings probably indicate serious deficiencies in health care systems and the knowledge of the population about the associated disease processes. ☐

Acknowledgments

The authors thank the participants from the Hawaiian community on Molokai and the members of the Na Pu'uwai not represented on the authors list, including Billy Ikutigawa, Jane Lee, Noelani Joy, Kekuni Blaisdell, and others, whose hard work made this study possible.

This research was supported by the Hawaii Heart Association, the Straub Trust, Alu Like, and the Office of Hawaiian Affairs, Honolulu, Hawaii.

HIV Risk Behavior Reduction following Intervention with Key Opinion Leaders of Population: An Experimental Analysis

Jeffrey A. Kelly, PhD, Janet S. St. Lawrence, PhD, Yolanda E. Diaz, MSW, L. Yvonne Stevenson, MS, Allan C. Hauth, MA, Ted L. Brasfield, RTT, Seth C. Kalichman, BA, Joseph E. Smith, RN, and Michael E. Andrew, PhD

ABSTRACT

Background and Purpose. Peer norms influence the adoption of behavior changes to reduce risk for HIV (human immunodeficiency virus) infection. By experimentally intervening at a community level to modify risk behavior norms, it may be possible to promote generalized reductions in HIV risk practices within a population.

Methods. We trained persons reliably identified as popular opinion leaders among gay men in a small city to serve as behavior change endorsers to their peers. The opinion leaders acquired social skills for making these endorsements and complied in talking frequently with friends and acquaintances. Before and after intervention, we conducted surveys of men patronizing gay clubs in the intervention city and in two matched comparison cities.

Results. In the intervention city, the proportion of men who engaged in any unprotected anal intercourse in a two-month period decreased from 36.9 percent to 27.5 percent (−25 percent from baseline), with a reduction from 27.1 percent to 19.0 percent (−30 percent from baseline) for unprotected receptive anal intercourse. Relative to baseline levels, there was a 16 percent increase in condom use during anal intercourse and an 18 percent decrease in the proportion of men with more than one sexual partner. Little or no change was observed among men in the comparison cities over the same period of time.

Conclusions. Interventions that employ peer leaders to endorse change may produce or accelerate population behavior changes to lessen risk for HIV infection. (*Am J Public Health* 1991;81:168–171)

Introduction

Experience in many health promotion areas supports the importance of social influence as a determinant of population risk behavior patterns.[1-3] Gay men who successfully implement risk reduction report greater peer support for behavior change than their unsuccessful counterparts,[4-6] while beliefs that one's friends have already made precautionary changes and that these changes will be well accepted predict compliance with acquired immunodeficiency syndrome (AIDS) risk reduction recommendations.[5,6] Reductions in high-risk sexual behavior among homosexual men in urban centers appear linked to new norms in the gay communities of large cities which discourage high-risk activities such as unprotected anal intercourse and encourage precautionary steps such as condom use or other safer sex modifications.[7,8]

Persons frequently seek the advice of friends concerning steps needed to reduce risk for AIDS.[9] Diffusion of innovation theory posits that trends and innovations are often initiated by a relatively small segment of opinion leaders in the population.[10] Once visibly modeled and accepted by natural opinion leaders, innovations then diffuse throughout a population, influencing others. The purpose of this investigation was to experimentally test an AIDS prevention intervention based on diffusion of innovation/social influence principles. Because HIV (human immunodeficiency virus) risk behavior levels remain high among gay men in small cities[5,6,11] and because geographically isolated communities constitute compact environments where it is feasible to experimentally evaluate community-level intervention of this kind, the project targeted homosexual men in small cities.

Methods

Setting and Baseline Survey

The study was conducted late in 1989 in Biloxi and Hattiesburg, Mississippi, and Monroe, Louisiana, selected because they are relatively small (populations of 50,000 to 75,000 residents), separated by at least 60 miles from one another or from any other city of larger size, and because each city had one or two large gay bars. Due to the geographical isolation of the cities and the paucity of other meeting places, these clubs tend to attract large, stable crowds of homosexual men and serve as the primary social setting in each city's gay community. An earlier survey of men patronizing clubs in these cities revealed alarmingly high rates of high-risk sexual behavior.[6] AIDS incidence data for the cities are not compiled, but data from local health department HIV testing sites indicate relatively low seroprevalence rates (approximately 2 percent) among all men who seek testing in the cities. This suggests that HIV infection prevalence is still moderate but will increase unless behavior changes among gay men are quickly implemented.

From the University of Mississippi Medical Center, Jackson, MS. Address reprint requests to Jeffrey A. Kelly, PhD, Professor, Department of Psychiatry and Mental Health Sciences, Medical College of Wisconsin, 8701 Watertown Plank Road, Milwaukee, WI 53226. This paper, submitted to the Journal April 17, 1990, was revised and accepted for publication September 11, 1990.

To obtain baseline data on population AIDS risk characteristics, men entering each city's clubs were initially surveyed over three consecutive nights. The survey measure was completed anonymously and individually at small tables located near the club entrances; men who completed the questionnaire on one night did not complete it again during the same three-night sampling period. In addition to demographic information, the measure assessed:

- knowledge about AIDS risk behaviors and risk reduction steps using a 23-item true/false test[12];
- perceived social norms concerning the acceptability of adopting safer sex precautions measured by endorsement on 5-point Likert scales of five statements (example: "My gay male friends insist on using condoms when they have intercourse") and yielding scores of 5 to 25[5,6]; and
- personal sexual behavior occurring over the past two months, including number of occurrences and different partners for unprotected insertive and receptive anal intercourse, anal intercourse with condoms, and other low-risk practices (frottage, mutual masturbation, and similar activities). This measure was pilot tested extensively and has been successfully used in prior surveys of gay men's risk behavior.[5,6,11]

The same survey procedure was repeated in a second three-day sampling period four months later at each club in each city to establish baseline stability in population risk characteristics. A preliminary review of survey data revealed that AIDS risk knowledge scores were consistently high among men in each city ($M = 21$ of 23 items answered correctly) so basic knowledge items were deleted from subsequent surveys. Counts were made of the total number of men who entered clubs to determine the proportion of the entire population successfully surveyed.

Study Design and Intervention Procedures

Following baseline population assessments in all cities, one community (Biloxi) was randomly selected to receive the intervention while the other two communities served as comparison cities. The comparison cities received no specific intervention, although AIDS prevention posters and brochures were generally available in gay clubs in the cities. No significant differences in population risk behavior were found between the two comparison cities.

In the intervention city, a three-stage process identified, trained, and then contracted with popular opinion leaders among gay men to endorse behavior change to their peers.

Identification of Opinion Leaders: To identify key popular people, four club bartenders familiar with population members were trained to observe social interaction patterns within the city's gay clubs. Each made unobtrusive behavioral observations in the clubs for one week, recording first names and a physical identifier for 30 persons observed to socialize and be greeted positively most often by men in the clubs. Recording sheets were cross-matched for repeated mention; 36 of a total of 82 names received multiple nominations and were considered key popular people. Twenty-two were located, entered in the program, and asked to invite one friend also considered to be highly popular with gay men and not already a participant. The total training group consisted of 39 men and four women with a mean age of 30 years and a mean education level of 13.8 years; 91 percent of the group was White and 9 percent African-American or Hispanic.

Training the Opinion Leaders: The training consisted of four weekly, 90-minute group sessions led by a male and a female leader. In session one, the leaders reviewed basic epidemiology of HIV infection, high-risk behavior, and precautionary changes needed to reduce risk and misconceptions concerning risk. They discussed the steps that can be used to successfully implement risk reduction, including: keeping condoms readily available if sexually active; avoiding excessive intoxicant use before sex; discussing precautions in advance with sexual partners; resisting coercions to engage in high-risk practices; and self-reinforcing for behavior change efforts.

Session two described characteristics of effective health promotion messages: sensitizing others to the potential threat of AIDS; stressing that HIV infection can be prevented by behavior change; identifying specific behavior changes needed to reduce risk; suggesting strategies for implementing these changes; using self as an example in order to avoid a "preachy" tone (i.e. beginning statements with "I am learning to . . ." rather than "You should . . ."); and personally endorsing the positive value and desirable benefits of behavior change.

In the third session, leaders modeled conversational examples which incorporated the characteristics discussed in session two. Following discussion of the enactments, participants role-played how they would initiate conversations, incorporating these message characteristics. Group leaders and assistants observed this social skill rehearsal, providing feedback and suggestions. After becoming proficient in the role-plays, each participant identified four gay male friends with whom s/he could initiate an endorsement conversation in the next week. Monitoring forms were provided for recording descriptions of these conversations.

Session four reviewed outcomes of the real-life conversations; most participants reported positive reactions from others. The leaders and participants then problem-solved persons, settings, strategies, and times which would afford opportunities to initiate additional conversational contacts with other peers. All members agreed to initiate and monitor at least 10 more peer conversations over the next two weeks. The session concluded with further discussion emphasizing the participants' important role in stressing the benefits of behavior changes to prevent HIV infection among gay men in their own community. Of the 43 opinion leaders who began the intervention, 35 attended all the sessions.

Later review of participants' self-monitoring forms indicated that 371 peer conversations were monitored over the two-week period. This probably underestimates the number of conversations which actually took place because peer conversations were likely to have continued beyond the monitoring phase. In addition, before and after the training program, each opinion leader was asked to role-play standard, simulated peer educational conversations. Ratings of the tape recorded role-plays were made by trained judges, naive to whether practice conversations were pre- or postintervention. These rates revealed that, after training, the opinion leaders more frequently exhibited skills taught in the program (data available on request to author). These checks confirm social skill acquisition and conversational assignment compliance by the opinion leaders.

To stimulate opportunities for initiating peer conversations, posters with a traffic light logo (red, yellow, and green circles) but no printed explanation were placed throughout the clubs shortly before the end of the intervention. Each training participant was given a small lapel button with the same logo and asked to wear it. Participants reported that this cuing device led many people to inquire about the

TABLE 1—Measures of Behavior in Surveyed Populations Prior to Intervention and Behavior Change Postintervention

Behavior Characteristics[a]	Preintervention		3–6 Month Changes		Difference (95% CI)
	Intervention City	Comparison Cities	Intervention City	Comparison Cities	
Percent of Respondents Engaging in:					
Any Unprotected Anal Intercourse	36.9	40.4	−9.4	−2.9	6.5 (6.4, 6.6)
Unprotected Receptive Anal	27.1	30.9	−8.1	−3.7	4.4 (4.3, 4.5)
Unprotected Insertive Anal	31.5	31.5	−9.6	+0.4	10.0 (9.9, 10.1)
Percent of Anal Intercourse Occasions Protected by Condoms:					
Any Anal Intercourse	48.8	54.5	+6.5	−6.1	12.6 (12.5, 12.7)
Receptive Anal Intercourse	50.4	55.4	+8.0	−7.8	15.8 (15.7, 15.9)
Insertive Anal Intercourse	49.2	54.7	+5.2	−5.1	10.3 (10.2, 10.4)
Percent of Respondents Reporting Multiple Sexual Partners	42.4	38.2	−7.8	+1.9	9.7 (9.6, 9.8)

[a] In two months prior to survey point.

TABLE 2—Percentage Distribution for Number of Sexual Partners for Unprotected Anal Intercourse in Prior Two Months: Intervention and Comparison Populations Before and After Intervention

Number of Partners	Intervention City		Comparison Cities	
	Pre	Post	Pre	Post
0	70.7	80.0	68.8	70.9
1	7.1	5.2	7.9	8.4
2	4.2	3.4	3.5	3.7
3	2.0	1.0	4.0	3.4
4	1.9	1.3	6.5	6.6
5	2.6	0.9	2.5	4.0
6	2.9	1.2	1.3	0.8
7+	8.6	7.1	5.5	2.2

meaning of the symbol. These questions, in turn, stimulated opportunities to explain precautionary changes from the traffic light scheme (high-risk, moderate-risk, low-risk) and endorse these changes in the conversational style that was practiced in training. The lapel buttons also served as visual cues which reinforced the endorsement of behavior change by well-known and popular individuals.

Several months after the intervention's completion, participants were recontacted by telephone, encouraged to continue their peer education conversations, and commended for their continued efforts.

Determining Change in Population Risk Characteristics

Surveys of all male club patrons in all cities were repeated in the same manner as at baseline three months and again six months after the end of the training period. Responses of training participants were excluded. Intervention city men reported they were approached to initiate a mean of 7.1 conversations, demonstrating that the conversations encouraged in the training program occurred frequently.

Results

A total of 659 surveys were completed at the two baseline survey periods (intervention city N = 328, comparison cities N = 331) and 608 men completed surveys at the two postintervention periods (intervention city N = 278, comparison cities N = 330). This was an average of 81 percent (range = 68 to 88 percent) of all men patronizing each city's clubs during the survey periods. Between 24 and 47 percent of the men who completed measures on one occasion were the same men who completed them earlier; over 70 percent of respondents lived in the city where the survey was conducted. The mean age of all men surveyed was 29.1 years; the mean education level 14.9 years; 86 percent of men were White and 14 percent African-American or Hispanic. There were no significant differences between intervention and comparison city populations, nor were there systematic changes over time within a city's surveyed population, for these characteristics.

Table 1 presents behavioral characteristics for both the intervention and comparison cities before and following intervention with 95% CIs of the differences in behavior change. For purposes of brevity, results of the two baseline surveys and the three- and six-month postintervention surveys are averaged as a single figure. Populations in the intervention and comparison cities were initially comparable in risk characteristics. At the postintervention surveys, the proportion of men who engaged in unprotected anal intercourse decreased by about 30 percent from their initial levels. Much less change was evident in the population of men in the comparison cities. Similarly, there was an increase in proportion of all anal intercourse occasions when condoms were used only in the intervention city. Finally, the intervention produced a decrease in the proportion of intervention city men who reported having multiple sexual partners in the preceding two months, an effect not found in the comparison cities.

Table 2 shows the percentage distribution for number of sexual partners in the intervention and comparison populations before and after intervention. These results show some shifts reflecting an increased proportion of intervention city men who had either one or no sexual partner from pre- to postintervention and slight general decreases in the proportion of men who had two or more partners (Z

$= 1.66$, $p < .05$ for nonparametric Wilcoxon signed rank test).

Survey responses of the male opinion leaders, examined separately, showed that in the two months before training, 39 percent of opinion leaders engaged in unprotected anal intercourse; in the postintervention survey, 24 percent engaged in this practice.

Distinctive changes in social norm measure scores were not associated with the intervention; only a general and modest pre- to posttest increase in scores was found (from $M = 15.6$ to 17.0). However, intervention city men who refrained from unprotected anal intercourse reported in posttest surveys receiving health message conversations from peers more ($M = 6.3$ conversations) than men who still engaged in unprotected receptive anal intercourse ($M = 3.5$) or in any unprotected anal intercourse ($M = 4.8$).

Discussion

To the best of our knowledge, this constitutes the first report of an experimentally controlled study evaluating a community-level field test of an intervention for HIV risk reduction. This study found that engaging key opinion leaders popular with gay men in small cities to serve as behavior change endorsers to their peers, produced reductions in the proportion of men in the population who engaged in high-risk activities and produced concomitant, population-wide increases in precaution-taking. The magnitude of these shifts compares favorably to those commonly found following mass, community-based population intervention for other health behavior problems such as cigarette smoking and cardiovascular risk reduction. This suggests a cost-effective HIV prevention model which may be of benefit in interventions with gay men, intravenous drug users, adolescents, and other groups.

Several findings in this study were of particular interest. First, AIDS risk behavior knowledge scores were high among men in each city even before intervention, suggesting that lack of knowledge about AIDS was not a critical dimension in the populations studied and that intervention methods which induce behavior change implementation and social acceptability of changes are needed. Second, while we anticipated that the intervention would alter perceptions of social norms, the norm measure did not reflect changes parallel to the population behavior shifts. Generalized changes in sexual behavior may precede peer norm changes rather than cause the initial adoption of risk reduction. In that case, elements of the intervention responsible for population behavior change may have included frequent safety prompts delivered by credible peers, conversational dissemination of suggestions for implementing precautionary changes, legitimization of making risk reduction changes by opinion leaders, or other factors.

While the study's results are highly promising, a number of cautions must be raised. We studied only men who patronized clubs and relied on self-reports of behavior. However, the geographical isolation of the study cities, the stability of club populations over time, and the function of clubs as the major social setting for gay men in these communities supports the relevance of data collection at these sites. While self-report behavior measures are essential in large-scale HIV risk behavior research, other data corroborating population behavior change—such as changes in community STD (sexually transmitted disease) incidence, condom purchasing patterns, or HIV testing requests and infection incidence—are needed to substantiate future conclusions about intervention impact. Finally, only a small number of cities were involved in this demonstration. Wider-scale clinical field trials of such experimental models in multiple cities and with larger populations are needed to establish their generalizability. ☐

Motorcycle Licensure, Ownership, and Injury Crash Involvement

ABSTRACT

The interrelationships among motorcycle licensure, ownership, and injury crash involvement were investigated in a sample of 2,723 motorcycle drivers severely or fatally injured in California in 1985–86. Owners of motorcycles in such crashes ("driver-owners") were less likely to have valid licenses than a random sample of motorcycle owners who had not been in crashes (42 vs. 57 percent). Thirty-three percent of the crash-involved drivers had valid motorcycle driver's licenses; 39 percent were operating motorcycles they did not own ("driver-nonowners"). Driver-nonowners were less likely to be validly licensed than driver-owners (20 percent vs. 44 percent). The licensing rate of crash-involved driver-nonowners was 15 percent if the owner was also unlicensed. Rates of valid licensure were lowest among the youngest drivers. Virtually no crash-involved driver-nonowners under age 21 were licensed in cases in which the owner was also young and unlicensed. (*Am J Public Health* 1991;81:172–176)

Introduction

In most states a special license is required to operate a motorcycle on public streets and highways. There is evidence, however, that many of the motorcycle drivers killed or seriously injured in crashes did not have a license to operate a motorcycle. Hurt and associates* reported in an unpublished document that 46 percent of 900 motorcycle drivers involved in crashes in Los Angeles in 1976–77 were not validly licensed. Data from the US Department of Transportation's Fatal Accident Reporting System (FARS)** show that about 43 percent of motorcyclists killed on public roads or highways in the United States did not hold a valid motorcycle operator's license. In both reports, however, there was no information given on licensure status of motorcyclists not involved in injury crashes. Neither of these data sets provides information on whether the injured were driving motorcycles they owned, nor do they indicate whether lack of licensure was associated with increased crash risk. Barry[1] noted 20 years ago that a substantial percentage of operators of motorcycles involved in injury crashes had "borrowed" the vehicle, but the report did not include information on whether the motorcyclists were licensed.

The present study was designed to address the following questions:

- Do motorcycles owned by people without motorcycle licenses have greater likelihood of crash involvement?
- To what extent do motorcycle drivers in serious and fatal injury crashes have valid licenses? own the motorcycle they were driving?
- How does motorcycle licensure vary by whether the crash-involved driver owned the motorcycle ("driver-owner" vs. "driver-nonowner")?
- How is motorcycle licensure affected by the relationship between crash-involved driver-nonowners and owners, when other relevant factors are also controlled?

Methods

A valid motorcycle license in California is a "class 4" license or, more frequently, a motorcycle endorsement to another class of license. Motorcycle licensure requires a written examination and driving test for two-wheeled vehicles. Motorcyclist training was not required for any drivers prior to 1988.[2]

TABLE 1—Availability of Information on License Status and Percent Validly Licensed Motorcyclists among Owners and Drivers of Motorcycles in Study Group

Driver/Ownership Status	Total Number	Driver License Information Number (%) with Known License Status	% with Valid License for Operating a Motorcycle among Those with Known License Status
MOTORCYCLES IN CRASHES			
(a) Driver-owner	1,467	1,438 (98)	44
(b) Driver-nonowner	930	875 (94)	20
(c) Owner-nondriver	930	525 (56)	35
(d) Driver-unknown if owner	326	241 (74)	10
All drivers (a,b,d)	2,723	2,554 (94)	33
All owners (a,c)*	2,397	1,963 (82)	42
MOTORCYCLES NOT IN CRASHES			
Owners	13,638	8,648** (63)	57

*Excludes 326 cases in which ownership was undetermined.

**Subsequent results based on 6,965 motorcycle owners with license records (see Methods section).

on a California road, street, or highway were identified using the California Highway Patrol (CHP) Statewide Integrated Traffic Records Systems (SWITRS) and the original police reports. Crashes analyzed were limited to those in which the motorcycle driver was fatally or severely injured. A severe injury was defined by the CHP[3] as a cut or laceration of skin from which blood flows freely or saturates clothing, and also includes an extremity not in normal position, indicating fracture. In almost all cases, the injured driver was taken to a hospital by an ambulance or paramedic unit.*** Mopeds, scooters, all-terrain vehicles, other off-road vehicles, motorcycles of 1980 or earlier model years, and motorcycles with out-of-state registrations were excluded.

The SWITRS and the police reports provided data about the driver (driver's license number, age, sex, and extent of injury); the vehicle (vehicle license number, identification number—when recorded—make, and model year), and name and address of the registered owner.

Crash-Involved Drivers: The license status of injured drivers was determined from the California Department of Motor Vehicles (DMV) driver history file using the driver's license number recorded on the crash report. Drivers not licensed to operate motorcycles were classified as having a valid license for another class of vehicle, having a suspended or revoked license, or having no license at all.

Unlicensed operators included the following categories: no driver's license number recorded on the crash report, those whose license expired before the crash date, those whose license was first issued after the crash date, driver's license number beginning with "X" (indicating a DMV file with information on violations and crashes but no driver's license issued), and those with the DMV identification card only.

License status was classified as unknown if the driver was licensed in another state or country, if the driver was listed on the crash report as having an instruction permit or a temporary license, or if no computer record could be located for the driver's license number written on the crash report. If the driver's license history contained no record of a crash on the date of interest and the driver's birth date was inconsistent with the age on the crash report, the driver's license history data were not used and license status was also considered to be unknown.

Owners of Crash-Involved Motorcycles: In cases in which the crash-involved driver did not own the motorcycle, information on the license status of the owner was obtained. Because the owner's name and addresses—but not the owner's driver's license number—are on the crash report, it was necessary to match the name and address information on the crash report with name and address information on the California driver's license history file to identify the owners' driver's license number and obtain licensure information.

Owners of Motorcycles Not in Crashes (Comparison Group)

A comparison group composed of a random sample of 13,638 motorcycles, representing 4.5 percent of all registered motorcycles in California, was selected from the DMV vehicle registration file as of November 1, 1986. Inclusion in this sample was restricted in the same way as for motorcycles involved in crashes.

The chance of a motorcycle being included in the sample was proportional to the number of months in which it was validly registered in California during the study period. Once in the sample, motorcycles were assigned with equal probability to each of the 16 months in the study during which they were registered for use. This procedure resulted in a comparison sample that included every motorcycle that was registered during a month with equal probability for that month.

The driver's license history for the owners of motorcycles in the comparison sample was obtained in the following way. The status of the license was determined for the reference month to which the motorcycle was assigned for comparison. Of the initial sample of 13,638 motorcycles, name and address for the registered owner were available for 12,481 of them (92 percent). The driver's license number was located for 8,669 of the 12,481 (69 percent). Of the 8,669, a driver's license history file was located for 8,648 owners (99.8 percent). Based on the vehicle identification number, 8,510 of the vehicles were found to be true motorcycles. Driver's license histories of owners were randomly discarded until all months had a sampling ratio of 2.56 controls per case, the ratio found in the sparsest month. The final comparison sample included 6,965 vehicle owners.

Results

Licensure Information

The information available for subgroups of motorcycle owners and drivers is provided in Table 1. Licensure information was available for 94 percent of crash-involved drivers but for only 56 percent of owners of motorcycles in crashes who were not driving the motorcycle and for 63 percent of the comparison sample of owners of motorcycles not in crashes.

Licensure Rates

Table 1 also provides a summary of motorcycle licensure rates for the various groups of motorcycle owners and drivers.

***Personal communication, California Highway Patrol, April 1990.

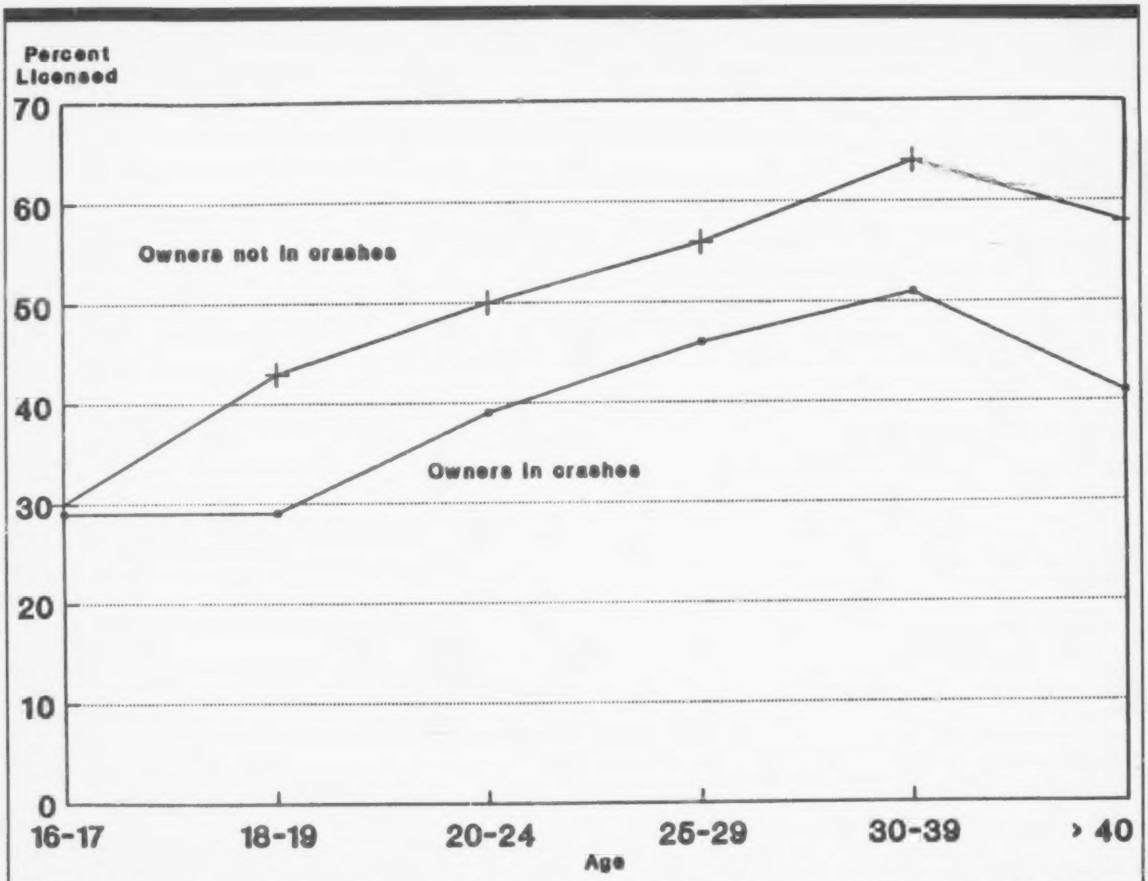

FIGURE 1—Percent of Validly Licensed Motorcyclists: Owners of Motorcycles in Crashes vs. Owners of Motorcycles not in Crashes, by Age

Owners: Owners of motorcycles in crashes were less likely to have valid licenses than motorcycle owners not in crashes (42 percent vs. 57 percent, odds ratio [OR] = 0.53, 95 percent confidence interval [CI] = 0.48, 0.59). Owners of crashed motorcycles were younger than the comparison group of motorcycle owners: 44 percent were under age 25 compared with 22 percent of the comparison group (OR = 2.86, CI = 2.58, 3.18). Owner licensure rates in both groups increased with age until age 40; fewer owners age 40 and over were licensed than owners ages 30-39. Figure 1 shows that the younger age of owners of crashed motorcycles did not account for the relationship between owner licensure and crash involvement. At all ages, owners of crashed motorcycles were less likely to be validly licensed than owners not in crashes (OR = 0.60, CI = 0.54, 0.66).

Owners of motorcycles in crashes who were operating the motorcycle were also less likely to be validly licensed than motorcycle owners not in crashes (44 vs. 57 percent, OR = 0.59, CI = 0.53, 0.66).

Drivers: Overall, 33 percent of crash-involved drivers were validly licensed. Valid licensure was strongly associated with age. The lowest licensure rate was among those under age 20 (18 percent); the highest rate was among those age 40 and older (51 percent).

Thirty-nine percent of the drivers were operating motorcycles they did not own, and they were less likely to be licensed than driver-owners (20 percent vs. 44 percent, OR = 0.31, CI = 0.26, 0.38). Driver-nonowners tended to be younger than driver-owners (63 percent were under age 25 compared with 47 percent of driver-owners; OR = 1.97, CI = 1.65, 2.34), but as shown in Figure 2, the differences in licensure rates between these two groups held, regardless of age (OR = 0.35, CI = 0.29, 0.43).

Among crash-involved drivers without valid licenses, 53 percent had a license to drive a passenger car but did not have a motorcycle endorsement, 31 percent did not have a license to drive any kind of motor vehicle, and 16 percent had suspended or revoked licenses.

Owner-Driver Pairs

Table 2 displays the percentage of validly licensed driver-nonowners by age, motorcycle owner license status, and the relationship between the driver and the owner. Older owners are defined as those who are more than 10 years older than the driver. Overall, in 56 percent of the 517 pairs, neither driver-nonowner nor owner was validly licensed. Valid driver licensure increased with driver age and with having a licensed owner. When owners were licensed, 27 percent of the drivers held valid licenses. When owners were unlicensed, only 14 percent of the drivers were licensed.

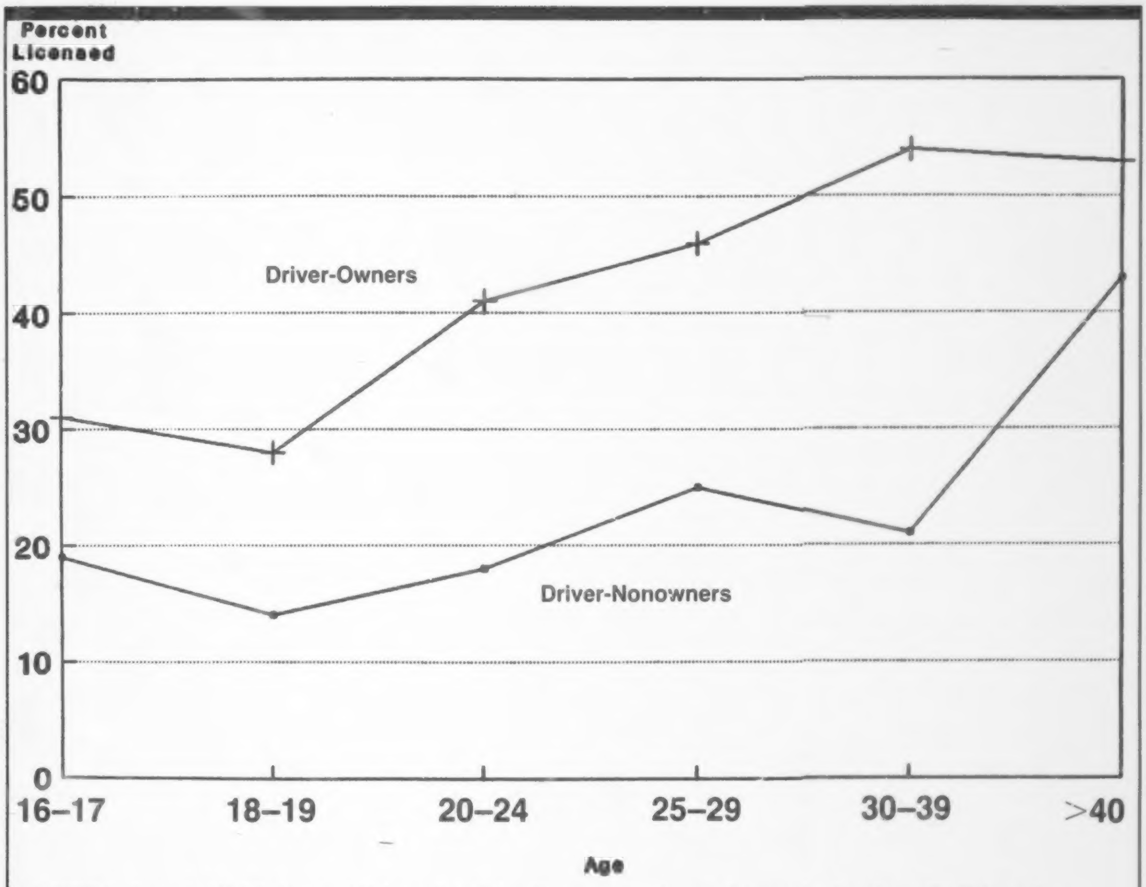

FIGURE 2—Percent of Validly Licensed Motorcyclists: Driver/Owners in Crashes vs. Drivers who do not own the Motorcycle

The data were analyzed using a log-linear model that included the three factors shown in Table 2 plus the interaction between motorcycle owner license status and the relationship between the driver-nonowner and the motorcycle owner. A greater proportion of drivers were licensed to operate a motorcycle if they were older and if the owner was licensed. More drivers were licensed if the owner was at least 10 years older than the driver and had the same last name or address as the driver, and fewer drivers were licensed when the owner was within 10 years of the driver's age and had a different last name and address.

Discussion

The proportion of unlicensed injured motorcycle drivers (67 percent) identified in this study is extraordinarily high compared with the proportion of fatally injured motor vehicle drivers (11 percent) in the US Fatal Accident Reporting System (FARS).[4] Our results also indicate that motorcycles owned by people without motorcycle licenses are more likely to be in crashes than motorcycles owned by people with valid motorcycle driving licenses. The results strengthen earlier, incomplete findings by Hurt and associates and FARS that most motorcyclists in crashes, especially young motorcyclists, are not validly licensed. In addition, those driving motorcycles they did not own were likely to be unlicensed, especially if the owner was also not licensed to operate a motorcycle.

The results also show that driver age, the use of someone else's motorcycle, and borrowing from an unlicensed owner are independent factors affecting valid licensure. Among young motorcyclists who crashed on motorcycles that were owned by other young and unlicensed motorcyclists, virtually none was validly licensed.

Unavailable data may alter somewhat the percentages presented. Licensure data were available for most of the drivers, but the driver's license status of only about 60 percent of the owners of motorcycles crashed by another operator and the random sample of owners of motorcycles not in crashes was known. This occurred usually because the name and address of the owner could not be matched with a name and address on the driver's license file. This linkage can fail for various reasons, such as a change of address by the owner. It is not known whether owners who could not be traced had a different percentage of valid licensure than those successfully traced.

Several countermeasures can be considered for reducing the crashes associated with invalidly licensed motorcycle owners and drivers. Requiring proof of valid licensure as a prerequisite for purchasing a motorcycle would reduce the extent to which owners and drivers are not

TABLE 2—Percent of Motorcycle Driver-Nonowners Validly Licensed by Owner Relationship to Driver, Driver Age, and Owner License Status

Owner Relationship to Driver	Owner Licensure Status	Driver's Age		
		16–19	20–24	25+

properly licensed. Motorcycle driving by invalidly licensed people might be reduced by stepping up enforcement of licensure laws and/or providing more stringent penalties for lack of licensure. Penalties against the owners of motorcycles driven by invalidly licensed drivers could deter owners from allowing such people to operate their motorcycles.

If applied, these measures could change the behavior of motorcycle owners and operators in one of two ways: these people can avoid sanctions either by obtaining the proper license or by not driving.

Measures that merely force licensure but do not change the amount of driving may have no effect on crashes. When existing licensure and training programs have been formally evaluated based on random assignment, the programs have not been shown to be effective in reducing crashes.[†,††] Thus, sanctions applied to unlicensed drivers and owners are more likely to be effective if they reduce driving than if they merely shift unlicensed driving to licensed driving. If the measures reduce exposure, they will reduce crashes, especially of young, novice, unlicensed drivers on borrowed bikes. □

Alcohol Use and Abuse in Random Samples of Physicians and Medical Students

William E. McAuliffe, PhD, Mary Rohman, PhD, Paul Breer, PhD, Grace Wyshak, PhD, Susan Santangelo, BA, and Elizabeth Magnuson, MS

ABSTRACT

Background. This study sought to resolve conflicting views about whether physicians are especially prone to alcohol abuse.

Methods. Using an anonymous, mailed questionnaire on substance use, we surveyed 500 physicians, 510 pharmacists, and 974 of their students. The physicians and pharmacists were selected randomly from the state society's membership lists, and students selected were from local school lists. Follow-up surveys were sent to nonresponders at two-week intervals.

Results. The physicians and medical students did not drink especially heavily and were no more vulnerable to alcoholism than were their counterparts in pharmacy and other professions. Physicians differed from pharmacists in their style of drinking (greater frequency, smaller quantity), but not in total amount of alcohol consumed. Drinking habits among physicians were not associated with medical specialty or type of practice, but were positively related to gender (males drank more than females) and to age (older doctors were more apt to qualify as heavy drinkers than were younger doctors).

Conclusions. Physicians were no more likely to abuse substances nonmedically than were other professionals. Any group in which alcohol use is nearly universal incurs a risk of abuse and impairment that cannot be ignored. (*Am J Public Health* 1991; 81:177–182)

Introduction

The authors previously presented evidence that many physicians, pharmacists, and their students have used controlled drugs for self-treatment and nonmedical purposes.[1] In his commentary, Lewis[2] cited the authors' failure to include alcohol use in their report. Some authors[3–5] have concluded that physicians are especially prone to alcoholism, while others[6–9] have concluded the opposite. Brewster[6] identified methodological flaws and contradictory findings in studies comparing physicians to other groups regarding cirrhosis mortality[10–13] and hospital admissions for alcoholism.[14–19] She concluded that surveys of physicians regarding alcohol use produce the most valid comparisons.[6,*] Our search of the literature revealed that few surveys have been reported to date,[7,8,20–25] and these have been limited by either small,[7,20,21] selective,[20,23] or nonrandom samples;[8,21,24] lack of anonymity for respondents;[21] incomplete measures;[27] minimal reporting of alcohol results;[22] or absence of comparable data on nonphysicians.[7,24,25] Studies of medical students suffered from similar limitations,[26] but recent studies have improved our knowledge substantially.[7,27–34]

This article presents a comprehensive picture of current and lifetime physician alcohol use and abuse from surveys of doctors and medical students, with comparative data on pharmacists, pharmacy students, and lawyers. The article also describes how physicians' drinking varies by medical specialty, type of practice, gender, and age.

Methods

The bulk of the data come from a previously described,[1] mailed, questionnaire survey (November 1984) of 500 physicians randomly sampled from the membership (8,400) of a state medical society, and 504 medical students randomly drawn from medical schools (combined enrollment of 1,438) in the same state. Approximately 73 percent of the state's physicians were society members in 1984. Comparative data come from a sample of 510 pharmacists randomly selected from the membership (1,270) of the state's pharmaceutical society and 470 pharmacy students randomly drawn from area schools (combined enrollment of 1,160). Each mailing packet contained a questionnaire, a letter assuring anonymity, and a post card with instructions to return it separately so that names could be removed from the follow-up mailing list. Second and third mailings and a reminder phone call to nonrespondents followed at two-

week intervals. The Committee on the Use of Human Subjects in Research at the Harvard School of Public Health approved the procedures.

Measures of Drinking Behavior and Problems

Responding to fixed alternative items, subjects qualitatively characterized their drinking since entering college, recorded whether they currently or ever had a drinking problem, and how frequently they experienced specific dysfunctions due to drinking (Table 2). For analysis we divided dysfunctions into "minor" and "major." Subjects also reported how often they drank in the past year (frequency) and how many drinks they typically consumed on each occasion (quantity). One drink was defined as 12 oz of beer, 3.5 oz of wine, or 1 oz of liquor. From those quantity/frequency reports, the investigators constructed a typology of current drinking patterns using the cutoff for heavy drinking (61+ drinks per month) employed by other researchers.[35,36]

Alcohol Abuser and Potential Abuser Operationally Defined

"Alcohol abuse" included both pathological use and significant dysfunction due to drinking, in accordance with DSM-III criteria.[37] "Pathological use" meant an average of more than three drinks per day in the past year, characterizing self as a lifetime "problem" drinker, or admitting a past or current drinking problem. "Significant dysfunction" was operationalized as a score of at least three on a scale of *minor* dysfunctions *or* a score of at least one on a scale of *major* dysfunctions. Scores were computed by assigning zero for a response of "never," one for "once or twice," two for "sometimes," and three for "often," and then summing across the four items in each scale.

A "potential abuser" had to report a combination of "heavy" alcohol use and "some dysfunction" due to drinking. "Heavy use" meant either an average of more than two drinks per day in the past year, or self-characterization as a lifetime heavy drinker. "Some dysfunction" was defined as at least one minor or major dysfunction due to drinking.

Statistical Methods

The methods used for comparing sample statistics included 95 percent confidence intervals and significance tests based on the t and chi-square distributions, multiple regression, and multiple logistic regression, depending on the number and measurement level of variables. The standard error calculations assumed infinite populations; all tests were two-tailed.

The Wyshak Sample

Unpublished quantity/frequency data will also be presented from a second survey of physicians and lawyers described elsewhere by Wyshak, *et al.*[22] This second physician sample was drawn randomly from the Department of Public Health's list of registered physicians in the same state five years before.

Results

Survey Response

After unlocatable and deceased respondents were removed from the four samples, the response rates were 70 percent for physicians, 78 percent for medical students, 76 percent for pharmacists, and 67 percent for pharmacy students. The figures for the two professional samples compared favorably with Wyshak's survey.[22] A few questionnaires returned by nonpracticing professionals and students who had left school were excluded to produce final samples of 337 physicians, 312 pharmacists, 381 medical students, and 278 pharmacy students. Responding physicians did not differ significantly from nonrespondents with respect to specialty, type of practice, sex, or geographical distribution. Only data on sex were available for the other three samples; medical school females responded more often than males (83 percent vs 75 percent, respectively), but no difference was found among pharmacists or pharmacy students. For the survey as a whole, how soon a respondent returned his/her questionnaire did not correlate with number of drinks in the past year, lifetime pattern of drinking, or reporting having ever had a drinking problem. However, doctors who reported having ever had a drinking problem tended to return their questionnaires later rather than sooner ($r = .09$; CI = $+.04, +.14$).

Despite the educational differences between the physicians and pharmacists, the samples were nearly identical in age (mean of 46 for both), gender (85 and 84 percent male respectively), and US citizenship (97 and 99 percent respectively). More pharmacists (79 percent) than physicians (66 percent) attended religious services. Medical students were older (25 vs 22 years), more often males (59 vs 44 percent), less religious, and more often American (99 vs 91 percent) than were pharmacy students. When appropriate, these variables are controlled in subsequent analyses, but since the samples were so similar, the adjustments made a difference only between practitioners and students (age was not controlled).

Drinking in the Last Year

There is no consistent evidence that physicians or medical students currently drink more than their counterparts in pharmacy (Table 1). While physicians and medical students reported drinking more *frequently* than the pharmacy samples, the pharmacy samples reported consuming greater *quantities* per drinking episode. In both medicine and pharmacy, practitioners drank more often than students but consumed less per episode. These zero-order differences remained when demographics were controlled.

There were only minor differences in current patterns of drinking among the four samples. Most respondents (e.g., 86 percent of doctors) in all four groups were

[c] Difference (p < .05) between either physicians and medical students or pharmacists and pharmacy students.

either light or moderate drinkers. The primary difference between the medical and pharmacy samples was in the percentage of abstainers (4 percent of doctors, 5 percent of medical students, 10 percent of pharmacists, and 11 percent of pharmacy students). Currently abstaining practitioners had a past or have a current (nonactive) drinking problem in some cases (one-third of physician abstainers, one-seventh of pharmacist abstainers). The major difference between practitioners and students was in the percentage of heavy drinkers (10 percent doctors, 12 percent pharmacists, 6 percent both medical and pharmacy students). When the amount of drinking was dichotomized at 61 drinks per month (cutoff for heavy drinking), the percentage difference between practitioners and students was estimated by logistic regression to be 5.7 (95 CI = 2.4, 8.9); that difference declined to 3.4 (0.1, 6.8) when gender and citizenship were included.[39]

Few respondents admitted to having a current drinking problem (from 1 to 3 percent; Table 1). There was, however, evidence of possible denial among heavy drinkers. While most of the respondents who admitted to a drinking problem also reported drinking very heavily (91+ drinks per month), the reverse was not true. Of the 13 physicians who reported drinking very heavily, only four saw themselves as having a current drinking problem, even though some of them admitted averaging over six drinks a day. Among pharmacists, only two of 17 very heavy drinkers reported a current problem. Among students, the figures were five of nine in medicine and zero of seven in pharmacy.

The Wyshak, *et al*, sample reported similar levels of drinking in the last year. With females eliminated to facilitate comparison, the mean of drinks per episode was almost identical (1.8 vs 1.7), and slightly more of Wyshak's sample reported heavy drinking (15.6 vs 12.4). Wyshak's physicians, however, averaged more drinking days per year (152 vs 126) than did ours (p < .05).

Lifetime Drinking Behavior and Problems

When asked to characterize their drinking pattern since entering college, most respondents (e.g., 91 percent of physicians) also described themselves as either light or moderate drinkers. Physicians differed significantly from pharmacists primarily in the percentage of abstainers (6 percent doctors, 12 percent pharmacists) as did medical students (7 percent) from pharmacy students (14 percent). There were no differences across the samples in the percentage of lifetime heavy or problem drinking. In all four samples, 4 percent of respondents admitted having ever had a drinking problem since entering college.

Dysfunction Due to Drinking

Although one in six physicians had worried at least once that he or she might be drinking too much, few reported a major dysfunction due to drinking (Table 2). Three percent of the physicians indicated that at least "once or twice" drinking had caused them to give less than their best patient care, and 3 percent had sought professional treatment for their drinking at some time in their careers. All told, 17 percent of physicians had ever experienced at least one dysfunction, while 10 percent had experienced two or more.

Physicians were more apt to worry about their drinking then were pharmacists (ratio of 1.9:1), and students were more likely than practitioners to report at least one minor dysfunction (ratio of 1.8:1). Most of the difference between practitioners and students, however, was in the two items that were worded differently for the two groups (work vs school).

Lifetime Abusers and Potential Abusers

Although physicians and medical students had slightly smaller percentages of combined abusers and potential abusers than the pharmacy samples (Figure 1), none of the samples differed significantly from the others on abuse, potential abuse, or the sum of the two. Controlling for gender and citizenship did not alter that finding. Of the 4 percent of physicians who abused alcohol at some time in their lives, half reported either no drinking or moderate drinking in the past year; the other half were still drinking heavily.

Subject Characteristics and Alcohol Use

Alcohol use was not related to medical specialty, type of practice (solo, group, and so on), citizenship, or religiosity, but was associated with both gender and age. Male physicians averaged 10.5 drinking days per month in the last year to only 6.5 for female physicians (CI for difference = 1.2, 7.0); male physicians also consumed more drinks per occasion (1.7 vs 1.2; CI for difference = 0.2, 0.8). However, like the male physicians, 4 percent of the female physicians qualified as ever being alcohol abusers, primarily on the basis of having a past drinking problem.

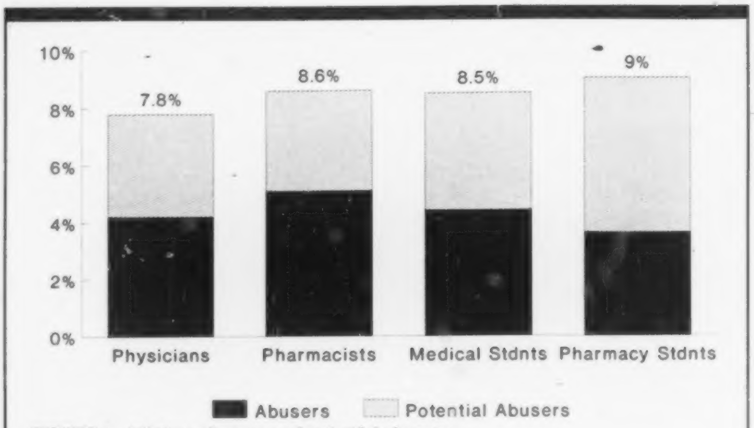

FIGURE 1—Lifetime abusers and potential abusers.

Abusers = pathological use plus impairment. Potential Abusers = pathological use plus minor impairment.

The gender difference in current drinking behavior was equally striking among pharmacists, but not among the student groups. Among medical students, males drank more than females in the last year, averaging 15.2 drinks per month to 10.4 for the females (CI for the difference = 0.8, 9.0). The sex difference, however, was only about a third as large as that for physicians.

Whereas gender bears the same relationship to drinking among our four samples as it does in the US population as a whole, the relationship between age and drinking is reversed (Figure 2, where females have been removed from all samples). Heavy drinking *decreases* with age for US males in general[35] (a finding confirmed in cross-sectional and cohort studies[40]), but it *increases* with age for both physician samples. Like physicians, pharmacists begin drinking much less than do US males, but jump quickly to a level close to that of the US population and remain at that level thereafter. Lawyers start somewhat lower than US males, peak sharply in their forties, and decline to a level slightly higher than physicians in their fifties and sixties.

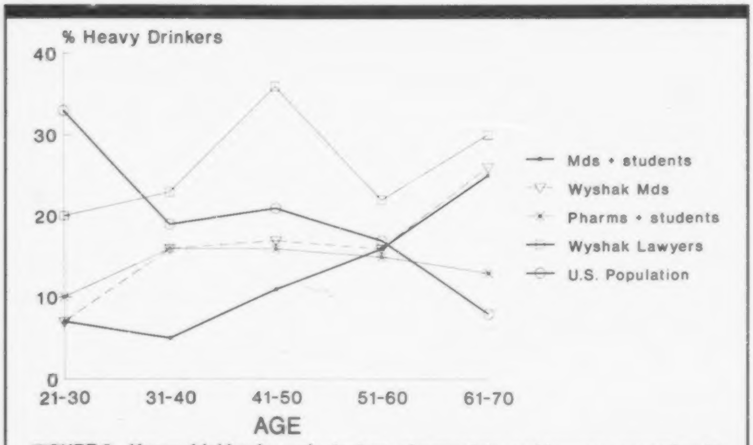

FIGURE 2—Heavy drinking by male doctors, pharmacists, and lawyers, according to age.

Note: US data from Clark and Midanik.[35]

Discussion

None of the present findings from our sample or the Wyshak, *et al*, sample indicates that physicians or medical students are especially prone to heavy drinking, alcohol problems, or alcohol abuse. The unique relationship between age and heavy drinking in these medical samples is confirmed by small surveys of residents and young physicians by the present authors[7] and another team in the same state,** and by physicians in another country.[25] It was also supported by data from a 20-year longitudinal study comparing a small sample of physicians with controls.[20] Analysis of data on job and life stress from this present study and our previous investigation[7] indicated that the association between physician age and drinking persists even after stress was controlled.

Several lines of argument support the validity of our survey methodology.[6] Recent reviews of the validity of self-report alcohol consumption data have found that they are generally valid.[41–44] Eight studies of clinical populations (i.e., individuals with a drinking problem) revealed "a high degree of agreement between patients and collaterals (family members) with no consistent direction of error."[41] Five nonclinical population surveys "yielded somewhat similar findings."[41]

There is conflicting evidence regarding the possible biasing effect of survey nonresponse. One study of physicians[45] found that attaining a survey completion rate higher than that found here had little effect on the results. Another investigation[46] reported no systematic relationship between probability of response and amount of alcohol consumption. Two other studies (one on cigarette use[47] and another on alcohol use in Sweden[42]) found that heavy users were more likely than light users to be nonrespondents. The close match between our sample and the medical society's members, and the generally weak correlations between drinking measures and promptness of response to our survey by doctors, suggests that any bias in the present study is probably small.

While severe alcoholics who are no longer practicing medicine may have been omitted from the sampling list, research tells us that impaired physicians rarely drop out of medicine or do so only briefly.[48] During 1984, the state from which the

---

**Gortmaker SL, Cheung L, Cleary P, Lampert S, Peterson N, Wechsler H: Results of the 1986 Harvard Health Survey at the Harvard School of Public Health, unpublished.

samples were drawn revoked the licenses of fewer than five physicians per 10,000 for all reasons.[49]

If the prevalence of alcohol use and abuse among physicians has been underestimated because of nonrespondents, that bias is probably no less true of pharmacists or medical students and pharmacy students. Since there is no reason to suspect *differential* bias, the results showing physicians and medical students to be no more vulnerable to alcoholism than pharmacists and pharmacy students are most likely valid. However, because of the nonresponse bias that has sometimes been found in surveys,[43,45,47] figures on the absolute prevalence of alcoholism for physicians and nonphysicians alike should be considered conservative.

Although the weight of evidence here and in previous studies[7,8,22,23,31,50,52] indicates that physicians and medical students are no more apt to abuse alcohol than are members of other professions, it is of some importance to the medical profession that, given the critical nature of their work, physicians are as vulnerable as their peers. The importance of the impaired physicians movement remains as an effective and humane model for handling problems of addiction. The findings reported here can best be used to remind us all that in any group where alcohol use is nearly universal and use rates are more than nominal, the risk of abuse and impairment cannot be ignored. ☐

Comments Sought on Product Safety Aspects Examination

The Board of Certified Safety Professionals (BCSP) has offered the Product Safety Aspects Examination since October 1981. In that nine-year period, very few candidates for certification have selected this specialty examination. Currently, there are only 25 Certified Safety Professionals certified in Product Safety Aspects.

Maintaining a good quality examination is costly. The number of candidates taking the Product Safety Aspect Examination has been so small that the fee income from the candidates who take it does not cover the costs associatied with its development and maintenance.

Because of the limited interest and the cost of maintaining the examination, BCSP is considering whether or not to offer Product Safety Aspects as a specialty. In making this decision, the Board is attempting to determine if the demand for the examination will change in the future or if there are special circumstances that would justify its continutation even with a small number of candidates. Examples of factors which could result in increased demand for the examination are changing regulatory requirements or increasing employer/client emphasis on certification in Product Safety Aspects.

To assist in making this decision, the BCSP is soliciting comments and opinions from all interested parties. Comments on this issue may be submitted to: Michael K. Orn, CSP, Executive Director, Board of Certified Safety Professionals, 208 Burwash Avenue, Savoy, IL 61874-9510; Tel: (217) 359-9263; Fax: (217) 359-0055.

Effects on Serum Lipids of Adding Instant Oats to Usual American Diets

ABSTRACT

This study was designed as a test of the serum lipid response and dietary adaptation to recommended daily inclusion of instant oats in an otherwise regular diet. Hypercholesterolemic adults were randomly assigned to a control or intervention group. Participants in the intervention group were given packages of instant oats and requested to eat two servings per day (approximately two ounces dry weight), substituting the oats for other carbohydrate foods in order to maintain baseline calorie intake and keep weight stable. Serum lipids were measured in blood collected by venipuncture at baseline, four weeks, and eight weeks. Baseline mean total cholesterol (TC) levels were 6.56 mmol/L and 6.39 mmol/L for intervention and control groups, respectively. After eight weeks, mean serum total cholesterol of the intervention group was lower by −0.40 mmol/L, and mean net difference in TC between the two groups was 0.32 mmol/L (95% CI: 0.09, 0.54). Low-density lipoprotein-cholesterol was similarly reduced with mean net difference of 0.25 mmol/L (95% CI: 0.02, 0.48) between the two groups. Mean soluble fiber intake increased along with slight self-imposed reductions in mean total fat, saturated fat, and dietary cholesterol intake in the intervention group. Neither group changed mean body weight. Daily inclusion of two ounces of oats appeared to facilitate reduction of serum total cholesterol and LDL-C in these hyperlipidemic individuals. (*Am J Public Health* 1991; 81:183–188)

Introduction

Elevated serum cholesterol is an established risk factor for coronary heart disease (CHD).[1,2] About 1.5 million Americans have heart attacks each year. Evidence is extensive that lowering blood cholesterol reduces risk of heart attack, and slows, stops and even reverses atherogenesis.[2-7] The report of the National Cholesterol Education Program (NCEP) Adult Treatment Panel states that diet is the cornerstone of treatment for high blood cholesterol.[8] Epidemiological studies, controlled clinical trials, animal experimental data, and autopsy studies demonstrate that diet and plasma lipids are causally related.[9] Dietary fatty acids, dietary cholesterol, weight change, and water soluble fiber have all been observed to affect serum cholesterol.[10-12]

These and other studies have generated growing public interest in appropriate foods to help lower blood cholesterol. Physicians and other health professionals recommend reducing intake of total fat, saturated fatty acids, and cholesterol to maximize blood cholesterol lowering. A relatively simple step toward improving dietary behavior may be emphasis on daily inclusion of carbohydrate foods high in water soluble fiber, such as oats, to help displace some of the saturated fat and cholesterol containing foods. By advocating foods to eat rather than focusing solely on foods to restrict, dietary adherence and nutrient adequacy may be better achieved. To explore the efficacy and feasibility of this approach, this study was designed to measure the dietary changes and biochemical response of including moderate daily amounts of instant oats in the diet of free-living, hyperlipidemic men and women.

Methods

Participants

Men and women volunteers were recruited from a financial institution in Chicago. Capillary blood cholesterol levels were measured with use of the Reflotron* desk-top instrument, to confirm hypercholesterolemic status of individuals previously screened by the company and found to have serum cholesterol levels above 5.20 mmol/L. Eligibility criteria included: availability and willingness to follow study protocol, attendance at all data collection visits and completion of all food records, not on lipid-lowering drugs or anti-hypertensive medication, not diabetic, not pregnant or lactating, not greater than 1.5 times desirable body weight (1959 Metropolitan Life Insurance Weight Tables as standards), and not on a weight-loss diet. All participants signed informed consents. Participants were required to complete a three-day food record before the baseline data collection visit.

Data Collection

Individuals were randomized to one of two groups, stratified by sex and pre-

TABLE 1—Baseline Means and Standard Deviations for Group 1 and Group 2

	Group 1 Intervention	Group 2 Control
	n = 42	n = 38
Male/Female	21/21	19/19
Age (years)	42.9 ± 13.5	42.1 ± 11.9
Age Range (years)	25.0–76.2	22.2–66.9
Serum Total Cholesterol mmol/L	6.56 ± 0.82	6.39 ± 0.88
Low Density Lipoprotein Cholesterol mmol/L	4.58 ± 0.81	4.61 ± 0.73
Body Weight (kg)	76.2 ± 15.1	75.7 ± 13.4
Height (cm)	169.9 ± 10.8	169.8 ± 8.9
Body Mass Index (BMI)(kg/m^2)	26.2 ± 3.4	26.2 ± 3.8
Blood Pressure (mm Hg)	128/80 ± 14/10	129/79 ± 20/8

screen cholesterol level, above or below 6.34 mmol/L, prior to baseline visit. Group 1 was the treatment group and was asked to consume two packets (56.7 grams dry weight) of instant oats per day. This represented 5.6 grams of total dietary fiber per day, of which 3.4 grams was insoluble fiber and 2.2 grams was soluble fiber. Group 2 served as the control group and was asked to maintain usual intake throughout the study. Food records, height, weight, blood pressure, and serum blood lipids were measured at baseline and two subsequent visits, after four and eight weeks. Biochemical variables assessed were serum total cholesterol, triglycerides, low density lipoprotein cholesterol (LDL-C), high density lipoprotein cholesterol (HDL-C), and very low density lipoprotein cholesterol (VLDL-C). Total cholesterol, HDL-C, and triglycerides were measured enzymatically (Technicon Autoanalyzer)** VLDL-C and LDL-C were calculated from the other lipids.[13] Body mass index (BMI) was calculated as weight (without shoes), measured in kilograms on a beam balance scale, divided by height in meters squared (kg/m^2). Blood pressure was measured twice by trained, certified technicians using a standard sphygmomanometer.

To avoid weight change, the intervention group was briefly instructed how isocalorically to substitute oats for other carbohydrate foods in their diet. Choice of preparation methods, time of day to consume the oats, and whether the packets of oatmeal should be eaten together or at separate times were left to the participants. No other dietary changes were advised. The intervention and control groups met separately.

Analyses

A two-tailed, two sample t-test was used for the analyses. The computer software program SPSS[14] was used.

Split samples of blood were analyzed for 10 percent of participants for quality control. Technical error was calculated by the formula:

$$TE = \sqrt{\sum_{i=1}^{N} d_i^2/2N},$$

where d_i is the difference between the ith pair of values for a person and N is the number of pairs; technical error divided by group mean × 100 was used to estimate percentage error. Food records were edited and coded by trained, certified nutritionists at the Nutrition Coordinating Center in Minneapolis. The National Heart, Lung and Blood Institute (NHLBI) nutrient data base (tape no. 16) was used for the nutrient analyses.[15] Blinded duplicates of 10 percent of all food records were sent for recoding and analysis for external quality control.

Subgroup analyses were performed comparing observed versus predicted cholesterol responses between groups based on change in Keys Scores. The Keys Score: $1.35 \times (2\,\Delta S - \Delta P) + 1.5\,\Delta Z$—where ΔS stands for the difference between the two diets in calories for saturated fatty acids (SFA), ΔP is the percent of calories for polyunsaturated fatty acids (PUFA), and ΔZ is the difference in the square root of dietary cholesterol in milligrams per 1,000 calories per day—can be used to predict group change in serum cholesterol level.[16] Analysis of covariance was used to measure mean changes in serum cholesterol adjusted for study group, sex, body mass index, and baseline cholesterol.[6]

Results

Prescreen total cholesterol levels were measured on 245 individuals. Of those, 111 met eligibility criteria, signed consents, and were randomized prior to the baseline visit. Failure to attend the baseline visit with a completed food record constituted a drop out. In all, 80 individuals completed all data collection visits; 14 were dropped from the Intervention Group and 17 from the Control Group. The majority of dropouts (18) did not bring food records and/or did not attend the baseline visit; other reasons: ill (5), wanted to lose weight (6), pregnant (1), and "oat product was too sweet" (1).

Mean age for the total cohort was 42 years (Table 1). There were no differences between the two groups in the characteristics measured including mean lipid levels.

As presented in Tables 2 and 3, after four weeks of intervention, Group 1 mean cholesterol was lower by 0.28 mmol/L and mean net difference, or the difference of the difference, between groups was 0.20 mmol/L. After eight weeks, mean net difference in total cholesterol was 0.32 mmol/L (95% CI = 0.09, 0.54) and in LDL-C was 0.25 mmol/L (95% CI = 0.02, 0.48). There were no significant differences between the groups in HDL-C or triglycerides.

Technical errors for serum lipid measurements were: total cholesterol, 1.6 percent, HDL-C, 2.7 percent; and triglycerides, 3.2 percent.

Reported dietary intake data are summarized in Table 4. At visit 3, Group 1 reported slightly decreased total fat, dietary cholesterol, and saturated fat. For the control group, there were slight increases in these dietary values. These opposite changes across groups resulted in an absolute difference in Keys Score of 5.31 (p = 0.039) from visit 3 to visit 1. Intervention group food records indicated increased intake of total, soluble, and insoluble fiber, iron, calcium, vitamin B_6, folacin, niacin, magnesium, and retinol. Group 1 reported consuming an average of 1.9 packets (54 grams) of instant oatmeal each day. This represented 5.3 grams of total dietary fiber of which 3.2 grams was insoluble fiber and 2.1 grams was soluble fiber. There were no reports of side effects from eating the oats.

TABLE 2—Group Means and Standard Deviations at Visits 1, 2, and 3 for Serum Lipids, Lipoproteins and Blood Pressure

Variables	Visit 1 Baseline	Visit 2 4 Weeks	Visit 3 8 Weeks
Total Cholesterol			
Group 1 mmol/L	6.56 ± 0.82	6.28 ± 0.92	6.15 ± 0.86
Group 2 mmol/L	6.39 ± 0.78	6.32 ± 0.84	6.30 ± 0.82
LDL-C			
Group 1 mmol/L	4.58 ± 0.81	4.24 ± 0.87	4.16 ± 0.83
Group 2 mmol/L	4.61 ± 0.73	4.39 ± 0.75	4.44 ± 0.77
HDL-C			
Group 1 mmol/L	1.29 ± 0.34	1.36 ± 0.28	1.28 ± 0.29
Group 2 mmol/L	1.26 ± 0.32	1.35 ± 0.26	1.30 ± 0.25
VLDL-C			
Group 1 mmol/L	0.70 ± 0.50	0.68 ± 0.42	0.71 ± 0.48
Group 2 mmol/L	0.51 ± 0.23	0.58 ± 0.28	0.56 ± 0.24
Triglycerides			
Group 1 mmol/L	1.52 ± 1.09	1.48 ± 0.92	1.54 ± 1.04
Group 2 mmol/L	1.12 ± 0.51	1.26 ± 0.61	1.22 ± 0.53
Blood Pressure (mm Hg)			
Group 1	127.9/80.3 (± 13/10)	121.8/80.8 (± 11/8)	123.5/77.0 (± 14/11)
Group 2	129.1/79.1 (± 20/8)	124.8/80.0 (± 11/8)	124.2/77.2 (± 13/9)

Group 1 = Intervention (oats), n = 42.
Group 2 = Control, n = 38.

Mean group difference in body mass index from visit 1 to visit 3 was not significant (Table 4). Average weight change from visit 1 to visit 3 was less than one pound with a slight decrease in Group 1 and increase in Group 2. Blood pressure changes also were not significant (Table 2).

Subgroup analyses explored possible differences in cholesterol response according to baseline median levels of serum total cholesterol, BMI, Keys Score, and sex (data not shown). Greater reductions in total cholesterol were observed among those individuals above the baseline median serum total cholesterol level of 6.34 mmol/L and below the median BMI of 26.17. Men and women in the intervention group experienced similar reductions in serum total cholesterol. In regression analysis to adjust for baseline total cholesterol, sex, BMI, and study group (Table 5), serum total cholesterol at visit 3 was significantly different between the two groups. Changes in serum cholesterol from visit 1 to visit 3 were also significantly different between the two groups, independent of sex, changes in BMI, and the baseline serum cholesterol.

Discussion

In this study, consumption of a moderate amount of instant oats in the daily food pattern fostered blood cholesterol lowering in hyperlipidemic individuals. The data suggest that dietary adaptation to the practice of regularly eating oats potentiates favorable effects on blood total and LDL-cholesterol levels as well as on nutritional status by reducing intake of total fat, saturated fat, and cholesterol without weight gain and improving intake of commonly deficient nutrients, i.e., iron, calcium and vitamin B_6. Participants appear to have, at least in part, substituted oats for other carbohydrate foods isocalorically, rather than simply adding oats to the baseline intake. Proposed mechanisms for the effect of oats relate to soluble fiber's capacity to bind bile acids and interfere with fat absorption, to increase fecal excretion of bile acids affecting hepatic secretion of lipoproteins and to ferment colonic bacteria, thus forming gases and short chain fatty acids and affecting hepatic cholesterol synthesis.[11,17]

Our group has previously reported that in a free living, normolipidemic population, 2 oz. (56 grams) of oatmeal or oat bran led to additional decreases in serum cholesterol of 4.2 to 5.3 mg/dl (adjusted for the reduction in the control group) over what was attributed to dietary fat and cholesterol modification.[18] This finding was confirmed by a follow-up study where the addition of 2 oz. of oatmeal decreased serum cholesterol 4.7 mg/dl more than what was achieved by a fat-modified diet alone.[19] Subgroup analysis further showed greater reductions in participants with higher baseline serum cholesterol levels.[19] Other intervention studies in free-living, hypercholesterolemic individuals have shown that one cup of oat bran plus five oat bran muffins daily (100 grams oat bran) induced a significant decrease in plasma cholesterol.[20]

A review of intervention studies in this area noted that addition of soluble fiber from oats, oat bran, legumes, pectin, guar, or locust bean gums has been reported to reduce plasma total cholesterol by 6–19 percent.[10] Particularly in hypercholesterolemic individuals, addition of oats has been reported to induce total cholesterol and LDL-C reduction.[21,22] The combination of a fat modified diet plus regular intake of oat bran by hyperlipidemic individuals was also shown to be as effective in cholesterol lowering as cholestyramine resin or colestipol with fewer side effects and less cost.[23]

More recently, Swain, *et al,*[24] reported blood cholesterol reductions of 7 to 8 percent in free-living, normolipidemic individuals (baseline mean serum cholesterol of 4.8 mmol/l) who consumed 100 gram supplements of oat bran or wheat cereal over six weeks in a crossover design study. The supplements were consumed in the form of muffins or entrees representing 35.6 percent (oat bran) and 40.8 percent (wheat cereal) of mean caloric intake reported during the two study periods. The authors concluded that isocaloric substitution of either oat bran or wheat for other carbohydrates produced similar blood cholesterol lowering effects in these normolipidemic individuals.[24] It was further suggested that previous studies including similar quantities (100 grams per day or more) of oat bran may have simultaneously induced quantitative and qualitative shifts in fat intake through replacement with oat bran and that these shifts were more directly responsible for

the observed serum cholesterol reduction than any effect of the oat bran itself. Demark-Wahnefried, *et al*,[25] similarly reported that both fat-modified and oat-bran enhanced diets lowered serum cholesterol by 10-17 percent among free-living, hyperlipidemic individuals (group mean baseline serum cholesterol level was 7.15 mmol/l). Relatively small sample sizes, differences in baseline blood cholesterol levels, differences in dietary assessment methodologies and incomplete nutrient data bases (lacking soluble versus insoluble fiber data) have made meaningful comparisons between such studies difficult.

TABLE 5—Regression Coefficients for Models of Visit 3 Total Serum Cholesterol (mg/dl) and Change in Total Serum Cholesterol (Visit 3 – Visit 1).

Dependent Variable = Visit 3 Total Cholesterol

Independent Variable	Coefficient	S.E. Coefficient
Group (0 = Control, 1 = Intervention)	−11.25	4.33
Total Serum Cholesterol Visit 1 (mg/dl)	.85	.07
BMI at Visit 3 (Kg/m^2)	.23	.65
Sex (0 = women, 1 = men)	−3.02	4.42

Dependent Variable = Change in Total Serum Cholesterol (Visit 3 – Visit 1)

Independent Variable	Coefficient	S.E. Coefficient
Group (0 = Control, 1 = Intervention)	−9.00	4.26

Change in BMI (Visit 3 – Visit 1) (Kg/m^2)	9.05	3.67
Sex (0 = women, 1 = men)	−2.18	4.14

From a public health perspective, perhaps the most important finding common among these studies is that the combined decreased fat and increased carbohydrate approach is practical, feasible, nutritious, and efficacious in lowering blood cholesterol among normolipidemic as well as hyperlipidemic individuals.

The study reported here measured self-imposed changes in dietary behavior and lipid response resulting from daily inclusion of instant oatmeal in the otherwise regular diet of hyperlipidemic men and women. Some of the earliest studies exploring the simple addition of fiber to a usual diet did not report specific dietary changes or displacement invoked when oats were substituted for other possibly high fat foods.[10,20,21,23] A more recent study incorporated large amounts of oats, constituting a major share of the caloric intakes thus limiting the participants capacity for other foods.[24] Documentation of the dietary changes associated with oat intervention serves to more accurately attribute blood cholesterol response to the relevant dietary factors. This study represents an initial attempt to document these changes. Results of nutrient analyses suggest that the recommendation to incorporate oats on a daily basis led to self-initiated changes in dietary fat intake, as well as increased intake of several essential nutrients. These results also illustrate the feasibility of eating moderate amounts of oats daily, without weight gain or side effects reported when greater amounts are consumed.[24] The differences between observed versus predicted blood cholesterol values in the intervention group suggest that the minor changes in dietary lipid intake alone did not completely explain the observed reductions. The instant oats, presumably by increasing soluble fiber intake, and the slight weight loss appear to have contributed to the overall serum cholesterol response. The relatively high drop out rate prior to baseline may have contributed to the imbalance in mean baseline blood cholesterol levels between groups that, although not statistically significant, may have somewhat confounded these results. Intensified intervention aimed at further decrease in intake of total fat, saturated fatty acids and dietary cholesterol, increased carbohydrate and reduction of excess body weight, would predictably further reduce serum cholesterol levels among these individuals.

More research is needed to clarify dose responses and evaluate long term effects of increased soluble fiber intake among hyperlipidemic and normolipidemic individuals. Potential differences in response to such regimens requires further exploration. ☐

Calendar for APHA 1991 Policy Development Process

The following schedule has been established for the development of APHA public policy resolutions and position papers in 1991. Full details of the Association's procedures for this activity can be obtained from:

AMERICAN PUBLIC HEALTH ASSOCATION, Attention: Richard Carson, 1015 Fifteenth Street, NW, Washington, DC 20005; (202) 789-5623

March 22 All proposed resolutions and position papers are due at APHA headquarters. They should be sent to the attention of the Joint Policy Committee. Proposals submitted via fax must be followed by hard copy within two days.

May 6–7 The Joint Policy Committee (JPC) meets in Washington to make an initial group assessment on each proposed policy statement. (Between March 22 and May 6, members of four reference committees will review each proposed policy statement. In addition, appropriate section chairpersons, SPIGs, and selected individuals are asked to review related proposed policy statements.)

May 24 All proposed statements are returned to authors with an inital assessment by the JPC.

June 28 Revised policy statements, to be considered by the 1991 Governing Council, must be back at APHA headquarters.

September Proposed policy statements are mailed to all APHA members in *The Nations's Health.* Copies are mailed to members of the Governing Council.

November 10 Annual Meeting—"Late-Breakers"—Submission deadline 6:00 pm (Sunday), for "late-breaking events." The chairpersons of the public hearings will be instructed that only those policy statements which address issues that have arisen between March 22 and the Annual Meeting will be considered as late-breaking events.

November 11 Annual Meeting—Public Hearings are conducted by the Reference Committees.

November 12 Annual Meeting—Joint Policy Committee meets in executive session to develop final recommendations for presentation of proposed resolutions and position papers to the Governing Council on Wednesday.

November 13 Annual Meeting—Governing Council votes on policy.

Validation of a Surveillance Case Definition of Carpal Tunnel Syndrome

Jeffrey N. Katz, MD, MS, Martin G. Larson, ScD, Anne H. Fossel, and Matthew H. Liang, MD, MPH

ABSTRACT

The National Institute for Occupational Safety and Health (NIOSH) has proposed a surveillance case definition for work-related carpal tunnel syndrome (CTS). The case definition requires the presence of median nerve symptoms; one or more occupational risk factors; and objective evidence of CTS including one of three physical examination findings or nerve conduction tests diagnostic of CTS. We evaluated the performance of the NIOSH case definition, restricting our analysis to cases in which physical examination findings served as the objective criterion. Nerve conduction studies were used as the gold standard. Seventy-eight workers were studied; 38 percent had CTS. The NIOSH case definition had sensitivity of 0.67 (95% CI = 0.57, 0.77), specificity of 0.58 (95% CI = 0.47, 0.69), and positive and negative predictive values of 0.50 (95% CI = 0.39, 0.61) and 0.74 (95% CI = 0.64, 0.84), respectively. Overall 38 percent of subjects were classified incorrectly. In a sample with a prevalence of 15 percent, as might be encountered in high risk workplaces, the positive predictive value would be 0.22. In conclusion, when physical examination findings serve as the objective criterion the performance of the case definition is modest reflecting the limited diagnostic value of its component tests and indicating that effective screening for CTS awaits improved diagnostic techniques. (*Am J Public Health* 1991;81:189–193)

Introduction

Carpal tunnel syndrome is a major problem in occupational health, particularly in occupations requiring highly repetitive and/or forceful hand motions.[1] Up to 15 percent of workers in the highest risk industries are affected annually,[2] 100 times more than expected in an age- and sex-adjusted population.[3] Costs per worker may exceed $15,000, including medical and indemnity expenses.[2,4]

Accurate and efficient diagnosis of carpal tunnel syndrome is important for research and clinical practice. Nerve conduction testing is generally regarded as the gold standard for the diagnosis of carpal tunnel syndrome.[5] The sensitivity of nerve conduction tests has been estimated at over 80 percent when compared with a clinical diagnosis of carpal tunnel syndrome in a community based study[6] and over 90 percent when compared with relief following surgery in 292 patients undergoing carpal tunnel release.[7] Electrophysiologic tests require 30 to 60 minutes, expensive equipment and experienced operators; thus, they may be inappropriate for many occupational surveillance efforts. Thermography[8] and vibrometry[9] are noninvasive but costly and have not been evaluated rigorously.

The clinical history and physical examination are inexpensive and simple to administer but are of limited value in the diagnosis of carpal tunnel syndrome. For example, nocturnal pain has a specificity of 0.28 and diminished two-point discrimination has a specificity of 0.32.[10] The Tinel and Phalen signs have sensitivities of 25–75 percent and specificities of 47–90 percent.[10–14] These data suggest that screening instruments comprised solely of historical and physical findings may not accurately identify workers with carpal tunnel syndrome.

The National Institute for Occupational Safety and Health (NIOSH) recently approved a surveillance case definition for work-related carpal tunnel syndrome[15] (see Figure 1). The NIOSH surveillance case definition of carpal tunnel syndrome requires that workers satisfy three criteria: symptoms of median nerve involvement; a history of occupational risk factors such as repetitive or forceful hand tasks or use of vibrating tools; and either the presence of physical examination findings—including the Tinel or Phalen signs or decreased pinprick sensation in the median nerve distribution of the hand—or diagnostic nerve conduction studies. To date the validity of NIOSH case definition has not been tested. The performance of the case definition is of particular interest when physical examination findings are used as the objective evidence required to fulfill criterion B (Figure 1). The purpose of this study is to test the NIOSH case definition in a sample of symptomatic workers. Physical examination findings serve as the sole objective evidence of disease (criterion B) in this

FIGURE 1—NIOSH Surveillance Case Definition of Work-Related Carpal Tunnel Syndrome*

Criteria A, B, and C must be met:

A. Symptoms suggestive of carpal tunnel syndrome: paresthesia, hypoesthesia, pain or numbness affecting at least part of the median nerve distribution of the hand.

B. Objective findings consistent with carpal tunnel syndrome:

Either, (1) One or more of the following physical findings: Tinel sign, Phalen sign, or decreased or absent sensation to pin prick in the median nerve distribution of the hand.

or, (2) Electrodiagnostic findings of median nerve dysfunction across the carpal tunnel.

C. Evidence of work relatedness: One or more of the following: Frequent, repetitive or forceful hand work on affected side; sustained awkward hand position; use of vibrating tools; prolonged pressure over wrist or base of palm; temporal relationship of symptoms to work or association with carpal tunnel syndrome noted in co-workers.

*adapted from reference 15

study and nerve conduction tests are used as the gold standard for the diagnosis of CTS.

Methods

An evaluation of clinical tests for carpal tunnel syndrome was carried out from January through June 1988. Details of the study have been reported.[10] Briefly, consecutive patients over 18 years of age with pain or paresthesia in the upper extremity who were referred to the Brigham and Women's Hospital Neurophysiology Laboratory were studied. A subset of this sample who were working or disabled as a result of their upper extremity condition are the subject of this report. Prior to neurophysiologic testing patients were evaluated by one of four examiners (a rheumatologist and three research assistants) who administered a questionnaire and performed a standardized physical examination. Examiners were blind to the results of nerve conduction tests.

Clinical data included demographic information, co-morbid conditions, occupation, and self-report of whether patients were exposed in their work to repetitive hand motion, vibration, or forceful wrist flexion or extension. The subjects also completed a hand pain diagram[16] which depicts dorsal and palmar views of both hands. Patients were asked to shade in areas corresponding to the location of their symptoms. Diagrams were rated blindly as "classic carpal tunnel syndrome," "probable," "possible," or "unlikely."

Moving two point discrimination[17] was performed with electrocardiogram calipers with tips set at four millimeters apart. The Tinel sign was performed by dropping the square end of a reflex hammer on the distal wrist crease. Pain or paresthesia in at least one of the first three digits constituted a positive response.[18] The Phalen sign was performed with the dorsal aspects of both flexed wrists in apposition for 60 seconds, and was considered positive if pain or paresthesia occurred in one of the first three digits.[19]

The presence or absence of CTS was established by the neurophysiologists with nerve conduction testing. The core protocol consisted of bilateral ulnar and median motor and sensory nerve conduction tests and electromyography of the abductor pollicus brevis. (Some subjects refused bilateral testing and/or electromyography.) Additional tests such as palm-to-wrist latencies[6] were performed according to the clinical circumstances at the discretion of the neurophysiologists. The neurophysiologists were blind to the results of physical examinations performed by the study investigators. The diagnosis of carpal tunnel syndrome required at least one of the following: median motor latency greater than 4.0 m/sec; sensory latency greater than 3.7 m/sec; and/or sensory velocity less than 50 m/sec. Ulnar nerve conduction and electromyography were used to exclude polyneuropathy, radiculopathy, and other diagnoses.

Criterion A of the NIOSH case definition (Figure 1) corresponded to a possible, probable, or classic rating on the hand pain diagram.[16] Criterion B corresponded to a positive Tinel or Phalen sign or diminished two point discrimination. The nerve conduction criterion was not used because our goal was to evaluate the performance of the case definition specifically when physical examination data are used as the objective criterion. Criterion C was satisfied if patients reported exposure on their jobs either to vibration, repetitive pinching, grasping, or wrist flexion or extension.

The sensitivity, specificity, odds ratio, positive predictive value (proportion with a positive test result who had carpal tunnel syndrome) and negative predictive value (proportion with a negative test result who did not have carpal tunnel syndrome) were determined for each of the diagnostic tests and for the NIOSH case definition.[20] Statistical analyses were performed with the chi-squared statistic using the SAS statistical package[21] on an International Business Machines P/S 2 Model 60 computer. Confidence intervals for sensitivity and specificity estimates were performed assuming a binomial distribution[22] and confidence intervals for predictive values were calculated with an iterative proportional fitting algorithm assuming a hypergeometric distribution.

Results

Seventy-eight symptomatic subjects were studied. Sixty-six were working at the time of evaluation and 12 were temporarily disabled as a result of their upper extremity problems. Patient characteristics are presented in Table 1. The mean age was 43.4 years. Sixty-three percent of subjects were female and 77 percent were White. Ten percent of patients had diabetes mellitus, 6 percent had thyroid disorders, and 4 percent had rheumatoid arthritis. These conditions were well controlled at the time of evaluation. Ten percent (eight patients) had prior carpal tunnel release surgery. Four of these eight patients were found to have carpal tunnel syndrome; in all four the previously operated hand was involved. Sixty-nine percent of subjects reported that their work involved repetitive hand motion, vibration, or forceful wrist flexion or extension. Thirty-eight percent of subjects had carpal tunnel syndrome documented by nerve conduction; diagnoses in the other patients are listed in Table 1.

Table 2 depicts diagnostic performance features of the individual components of the NIOSH case definition and of the case definition itself. In univariate analyses the presence of symptoms in at least part of the median nerve distribution of the hand was highly sensitive for carpal tunnel syndrome (0.93 [95% CI: 0.87, 0.99]) but non-specific (0.25 [95% CI: 0.15, 0.35]). The presence of occupational risk factors was also sensitive (0.83 [95% CI: 0.75, 0.91]) but nonspecific (0.40 [95% CI:

0.29, 0.51]). The Phalen sign was similarly sensitive (0.73 [95% CI: 0.63, 0.83]) but non-specific (0.36 [95% CI: 0.25, 0.47]), while the Tinel sign was less sensitive (0.62 [95% CI: 0.51, 0.73]) but more specific (0.66 [95% CI: 0.56, 0.77]). Two point discrimination was the least sensitive (0.23 [95% CI: 0.14, 0.32]) and most specific (0.82 [95% CI: 0.74, 0.91]) test for carpal tunnel syndrome.

The individual criteria were combined according to the NIOSH surveillance case definition and compared to actual diagnoses confirmed by nerve conduction tests. The case definition had sensitivity of 0.67 (95% CI: 0.57, 0.77), specificity of 0.58 (95% CI: 0.47, 0.69), positive predictive value of 0.50 (95% CI: 0.39, 0.61) and negative predictive value of 0.74 (95% CI: 0.64, 0.84). Overall, 48 of 78 (62 percent) subjects were classified correctly by the surveillance case definition. Bayes' Theorem[20] was used to calculate the predictive values in a population with prevalence of 0.15, as might be found in high-risk industries. In such a population the positive predictive value of the case definition would be 0.22 and the negative predictive value would be 0.91.

Discussion

Carpal tunnel syndrome has been associated with a variety of occupations including meat packing,[2] aircraft and bearing manufacturing,[1,23] sewing,[24] grocery checking,[25] and many others. Epidemiologic studies relating carpal tunnel syndrome to specific occupations have been limited by the lack of uniform, valid criteria for case ascertainment. The diagnostic gold standard, nerve conduction testing, is not suitable for many large surveillance efforts. Furthermore, simple clinical tests are of limited diagnostic value.[10]

The proposed NIOSH surveillance case definition is an important step toward standardization of surveillance. The present study is the first validation of the case definition against verified cases of carpal tunnel syndrome. This study suggests that when physical examination findings serve as the objective criterion the case definition has important limitations and must be used carefully. In our sample of workers with upper extremity complaints the positive predictive value of the case definition was 0.50 (95% CI: 0.39, 0.61) and the negative predictive value was 0.74 (95% CI: 0.64, 0.84). These results indicate that half of workers satisfying the case definition did not have carpal tunnel syndrome while a fourth of subjects not satisfying the case definition did. Overall, 38 percent of subjects were classified incorrectly.

It is critical to note that predictive values vary with the prevalence of disease. Carpal tunnel syndrome was more prevalent in our sample (0.38) than in other reported groups of symptomatic workers.[26,27] In a hypothetical sample of workers with a prevalence of CTS of 15 percent the positive predictive value of the NIOSH case definition would be just 0.22.

In evaluating the usefulness of the case definition it is important to distinguish between epidemiological surveillance, which provides information about disease prevalence in target populations, and screening, which identifies individuals at risk of disease.[28] The NIOSH case definition is a surveillance instrument intended for "use by state health departments to facilitate standardized counting of cases"; it is not intended for clinical use.[15] In surveillance programs designed solely to identify high-risk workplaces, simplicity and low cost are paramount. False negative and false positive results may compromise estimates of risk in these settings but do not adversely affect individual workers.[28] Our data suggest that the NIOSH case definition would be suitable for occupational surveillance as it is simple, inexpensive and accurate in 62 percent of subjects in our sample.

In contrast, inaccurate results exact higher costs when tests are used to identify possible cases for further testing and treatment. Here the cost of false negative test results is withholding treatment from workers who might benefit. The costs of false positives include worker anxiety, work absenteeism,[29] and the expense of disproving the screening diagnosis (e.g. $200–500 for a physician visit and nerve conduction tests). The modest sensitivity (0.67) and specificity (0.58) of the NIOSH case definition suggest that it should be used carefully if at all in screening for affected individuals or in clinical practice.

Other combinations of tests performed in parallel or in series would produce different trade-offs between sensitivity and specificity.[30] For example, we have demonstrated that the combination of a probable or classic hand diagram *or* a positive Tinel sign has sensitivity of 0.82 (95% CI: 0.75, 0.89) and specificity of 0.50 (95% CI: 0.41, 0.59), while a probable or classic diagram *and* positive Tinel sign has sensitivity of 0.39 (95% CI: 0.30, 0.48) and specificity 0.89 (95% CI: 0.83, 0.95).[10] However, no individual test or combination of tests offers sensitivity and specificity over 0.70 (Table 2) reflecting inherent limits in the diagnostic value of clinical tests for carpal tunnel syndrome.[10]

This study has several limitations. Subjects were referred to a hospital labo-

TABLE 2—Diagnostic Performance Characteristics of the NIOSH Case Definition and Its Component Parts

ratory for neurophysiologic evaluation. Some may have had particularly severe carpal tunnel syndrome, raising the sensitivity of diagnostic maneuvers, or atypical syndromes lowering specificity.[31] While all subjects were working or disabled it is not clear what proportion of cases were unequivocally work-associated or whether the case definition would perform differently in such cases. Also, we limited our analysis to cases in which criterion B was satisfied by physical examination rather than nerve conduction findings. Thus our analysis likely underestimates the specificity of the case definition. In addition, while nerve conduction tests are the best gold standard available, false negatives are well documented[7] and the false positive rate is not precisely defined, raising the possibility of misclassification error. Furthermore, occupational risk was estimated on the basis of self-reported exposure to vibration and repetitive finger and wrist flexion which is less accurate than detailed ergonomic analyses of job requirements. Finally, carpal tunnel syndrome is just one of a variety of occupation-associated upper extremity disorders. Symptomatic workers who do not have carpal tunnel syndrome may have other occupation-related cumulative trauma disorders[26] and might benefit from job modification and treatment.

We conclude that when the physical examination is used as the objective evidence to satisfy criterion B, the NIOSH case definition yields a significant number of false positive and false negative results. False positives will be especially common in groups of workers with a low prevalence of carpal tunnel syndrome. While the case definition appears to be suitable for epidemiologic surveillance, these inaccuracies make the case definition suboptimal for use in screening individual workers. The modest performance of the case definition reflects limitations inherent in its component tests, suggesting that accurate non-invasive testing for occupational carpal tunnel syndrome awaits the development and validation of better diagnostic technologies. ☐

Free Information Packet on Women and AIDS

In response to the growing need for information on women and HIV (human immunodeficiency virus)/AIDS (acquired immunodeficiency syndrome), the National AIDS Information Clearinghouse has increased its efforts to collect and disseminate information for and about women with HIV. Results of this effort led to the development of a new information packet which provides resources offered by the Clearinghouse. The Women and AIDS Information Packet developed by the Clearinghouse contains:

- A fact sheet describing Clearinghouse resources and services for women: e.g. to locate funding opportunities for women's programs or to find child care and housing assistance programs.
- Customized, topical searches of Clearinghouse databases: a selected list of educational materials for professionals concerned about HIV and AIDS and women; a list of materials for use in HIV education activities with women; a list of organizations offering services for women.
- A publications list of HIV and AIDS eductional materials offered by the Clearinghouse including brochures, posters, and videotapes.
- *A Selected Guide to Information about Women and HIV/AIDS* for use by health professionals, graduate or undergraduate students, or other interested persons. The guide lists books, indexes, online information sources, newsletters, journals, directories, and organizations that provide information about women and AIDS.

To obtain the free information packet, contact National AIDS Information Clearinghouse, P.O. Box 6003, Rockville, MD 20850; Toll-free: 1-800-458-5231, TTY/TDD: 1-800-243-7012, FAX: 1-301-738-6616; International line: 1-301-217-0023; Hours: 9am–7pm, EST, M–F.

Behavioral, Health and Psychosocial Factors and Risk for HIV Infection among Sexually Active Homosexual Men: The Multicenter AIDS Cohort Study

Lili Penkower, PhD, Mary Amanda Dew, PhD, Lawrence Kingsley, PhD, James T. Becker, PhD, Paul Satz, PhD, Frederick W. Schaerf, MD, PhD, and Kathleen Sheridan, JD, PhD

ABSTRACT

We examined whether 644 homosexual men who engaged in receptive anal intercourse were at particularly elevated risk for seroconversion if they also possessed specific behavioral, health or psychosocial vulnerability characteristics. Of 11 potential factors examined, heavy drinking, moderate to heavy drug use, and younger age were significantly related to seroconversion. These variables were also associated with an increased number of sexual partners, anonymous sex, and failure to use condoms. (*Am J Public Health* 1991; 81:194–196)

Introduction

Host vulnerability to illness is a complex process involving biologic, psychologic and social factors.[1-4] With regard to acquired immunodeficiency syndrome (AIDS), the etiologic agent, human immunodeficiency virus (HIV), is known and two behavioral factors, intravenous drug use and high-risk sexual behavior, transmit the virus.[5] Cofactors, increasing the likelihood that HIV-exposed individuals will become infected, have been suggested.[6-8] They include pre-existing health and behavioral factors (e.g., smoking, recreational drug use, alcohol consumption) and psychosocial factors (e.g., depression, lack of social support). We examined the impact of these variables on seroconversion risk in homosexual men engaged in high-risk sexual activity.

Methods

A sample of 1,045 bisexual and homosexual men was drawn from the total cohort of men enrolled in the Multicenter AIDS Cohort Study (MACS) between 1984–87. Participants in this four-site, longitudinal study were examined semi-annually (see Kaslow, *et al*,[9] for further cohort description). Our sample included all 209 men who: became HIV seropositive (HIV+) between 1984–87; and had tested seronegative (HIV−) six months before. Data from their last HIV− visit were utilized as "baseline" data; data from their first HIV+ visit were designated "follow-up" data. A comparison sample of 836 men, who were HIV− throughout 1984–87 and represented the four sites in the same proportion as the HIV+ sample, was randomly selected. For each HIV− man, we randomly selected two consecutive waves of interviews (six months apart) which we designated as the "baseline" and "follow-up" visits.

High-risk sexual behavior was defined as receptive anal intercourse in the prior six months.[10-12] At each interview, additional variables in the previous six months were assessed: number of sexual partners with whom respondents had receptive anal intercourse; number of anonymous partners; number of partners with whom respondents had used condoms during anal intercourse; and number of partners who themselves used condoms during anal intercourse with respondents.

Three categories of vulnerability factors, potentially affecting seroconversion risk, were measured at baseline (see first two columns of Table 1 for descriptive statistics). Absolute numbers of CD4+ cells were counted by direct immunofluorescence with use of monoclonal antibodies with an EPICS-C flow cytometer.[13] All variables were available for all men.

Results

At baseline, high-risk sexual behavior was reported by 87.0 percent of the 209

respondents who had seroconverted by follow-up, compared to 56.3 percent of the 836 seronegative men. The strong association between anal receptive sexual practices and seroconversion led us to focus on the 644 men who had engaged in high-risk sexual behavior at baseline.

After controlling for all other vulnerability factors, baseline heavy alcohol consumption, moderate to heavy drug use, younger age and, to a lesser extent, smoking were associated with seroconversion (Table 1).

We found no evidence that heavy drinkers, moderate to heavy drug users or younger men had fewer absolute numbers of CD4+ cells at baseline. Regarding the high-risk behaviors at baseline, however, heavy drinkers were indeed more likely to have engaged in receptive anal intercourse with more partners, had more anonymous sex, and were less likely to have either used condoms themselves or had partners who used condoms during anal intercourse. Similarly, moderate to heavy drug users reported more sexual partners and more anonymous sex. Younger men were more likely to have engaged in high-risk sex with more partners (data not shown; available on request to authors).

Discussion

The MACS' longitudinal design provided an unusual opportunity to examine data on behavioral, health, and psychosocial factors assessed prior to evidence of HIV seroconversion. Among men already at high risk for HIV infection, heavy alcohol consumption, moderate to heavy drug use and younger age further increased their likelihood of seroconversion by the follow-up visit.

Of these three factors, heavy alcohol consumption was most strongly associated with subsequent seroconversion. This finding is consistent with other evidence that alcoholics are at greater risk for infections of many types, and also have elevated morbidity and mortality rates.[18,19] Molgaard, *et al*,[20] have suggested that the importance of alcohol may derive from an association with impaired immunity and/or its behavioral effect on risky sexual practices. Our data suggest that its link to sexual practices may be of relatively greater concern. Thus, consistent with Kaslow, *et al*,[21] we found that CD4+ cells (albeit a limited measure of general immune function) bore little relation to heavy drinking. However, among men who all reported engaging in receptive anal intercourse heavy drinkers further elevated their risk of HIV exposure by engaging in sex with more partners, having more anonymous sex and by failing to employ condoms during high-risk sex.

Results for drug use and younger age were similar to alcohol. While drug users did not have lower CD4+ cell counts, they were more likely to engage in anonymous sex and had more sexual partners. It is noteworthy that, in comparison to all other drugs we examined, nitrite inhalant (popper) use was most strongly associated with seropositivity risk (odds = 11.83, 95% CI = 1.34, 3.04). Moss, *et al*,[22] recently reported a similar association. While no differences were observed in CD4+ cells among younger men, they were more likely to engage in high-risk sex with more partners.

We recognize several limitations in our study. First, a restricted number of potential risk factors were studied; many other factors (e.g., additional immune parameters, anxiety, nutrition, specific types of social support) remain to be investigated. Second, two of the psychosocial variables, self-esteem and social support, were each determined by a single question, and may have been inadequate measures of these constructs.

Nevertheless, our results suggest that efforts at controlling the spread of HIV infection may be improved by identifying individuals in high-risk groups whose other characteristics further heighten their already elevated likelihood of becoming infected. From a public health standpoint, it is imperative that the risks associated with substance abuse be recognized and that programs to educate and treat these addictions be made available and accessible. This study demonstrates empirically that individuals who engage in risky sexual practices and who are also heavy drinkers and/or drug users are at increased risk of becoming infected with HIV.

Responsible Alcohol Service: A Study of Server, Manager, and Environmental Impact

Beth Howard-Pitney, PhD, Michael D. Johnson, PhD, David G. Altman, PhD, Rodney Hopkins, MS, and Noreen Hammond

ABSTRACT

A responsible alcohol-service training program was evaluated for its impact on changing beliefs, knowledge, and behavior in 97 servers and 43 managers and on changing establishment policies that encourage safer drinking environments. The training program had a significant impact on changing the beliefs and knowledge of both servers and managers. Observation 4 to 6 weeks after training showed no effects on server behavior, but there was a tendency toward more establishment policies compared with controls. (*Am J Public Health* 1991;81:197–199)

Introduction

Deaths and injuries associated with driving while under the influence of alcohol are important public health problems.[1] In 1988, half of all traffic fatalities were alcohol related.[2] Making drinking establishments the site of interventions to reduce alcohol-related accidents has increased in popularity. Establishments may be held legally responsible for the behavior of customers who leave under the influence of alcohol[3–5]; and a growing number of states and cities require that all servers of alcohol receive training in responsible alcohol service.

Evaluations of several alcohol-service training programs suggest that they can have some impact on the drinking behavior of patrons.[6–9] While some programs focus primarily on teaching servers how to intervene with intoxicated customers, others seek to be more comprehensive by focusing on servers, managers, and environmental features of the establishment.[10–11] The Responsible Beverage Service (RBS) Training Program studied in the current research focused on all three of these elements.[12]

Methods

A newly expanded Utah law required that servers of alcohol and managers of establishments that serve alcohol participate in a state-certified training program every 3 years. Ninety-seven servers from 19 restaurants and bars and 43 managers from 21 establishments (26 different establishments in all) in Park City, Utah, attended a 1-day training session. Fourteen establishments matched on type and size were randomly selected from the remaining city establishments to serve as controls. They had not been exposed to this training, which was new in this community.

Servers and managers attended separate programs that taught the physical and behavioral effects of alcohol and strategies for providing more responsible alcohol service using a combination of lecture, role play, and feedback. Managers also received instruction on developing company policies to change the drinking environment. Participants completed pre- and post-training questionnaires measuring beliefs and knowledge about responsible alcohol-service practices. Further details are available on request.

One month following the RBS training, trained pairs of observers (each consisting of a man and a woman) with a mean age of 31 assessed server behavior and current policies in treatment and control establishments. The observers were blind to the treatment conditions, and the servers were unaware that they were being observed.

Observers first recorded ID-checking practices for the first three patrons both observers agreed looked 30 years old or younger (a practice taught to servers in the training) and environmental signs of responsible alcohol service in one establishment (described later). At a second establishment, one member of the pair drank three alcoholic beverages and tried to order a fourth in 1 hour. This amount ensured that the drinking observer was well on the way to being legally drunk (0.08 percent blood alcohol level in Utah). The consumption was such that if they followed their training, servers should have been able to interpret this drinking behavior as appropriate for intervention. The nondrinking observer recorded servers' interventions.

Results

T-tests on the pre- and post-test measures indicated that servers and managers

TABLE 1—Mean Number of Interventions by Servers in Treatment and Control Establishments

Type of Intervention	Treatment Servers (n = 22)	Control Servers (n = 19)
Communicated that server was aware of customer's drinking behavior	0.14	0.32
Slowed the delivery of drinks to the table	0.18	0.26
Suggested customer order a nonalcoholic drink or food	0.23	0.37
Offered to find transportation for an intoxicated customer	0.00	0.00
Explained that house policy does not allow the server to serve another alcoholic drink to customer	0.18	0.16
Verified that the nondrinking customer would do the driving	0.00	0.00
Refused to serve customer another alcoholic drink	0.23	0.16
Notified management if intoxicated customer became problematic	0.00	0.00
Mean of all interventions	0.95	1.26

Note: Data are based on observations by a nondrinking observer of server interventions with the drinking observation partner.

TABLE 2—Percent of Treatment and Control Establishments Showing Responsible Alcohol-Service Practices

Type of Practice Observed	Treatment Establishment (n = 13)	Control Establishment (n = 11)
Did not serve pitchers of beer or mixed drinks	46%	73%
Did not serve doubles	85%	82%
Did not offer happy hours	77%	82%
Had signs advertising low- or non-alcoholic drinks	38%	18%
Had transportation information	15%	9%
Had no employee drinking on the job	92%	73%
Mean of all policies	3.54	3.36

increased their knowledge and showed improvement in their beliefs that customers would respond favorably to responsible alcohol service and policies $p < .001$, all measures. The training was less successful in teaching servers and managers new strategies for intervening with customers, as reported in open-ended questions. (Data are available on request.)

Table 1 reports data on observations of interventions by servers. No differences were observed between treatment (n = 22) and control (n = 19) servers on any intervention nor on a summed average of eight possible interventions.

Observations of establishment practices were conducted in 13 of the 21 establishments with trained managers and 11 of the 14 control establishments (Table 2). Treatment establishments were more likely to have signs advertising low-alcohol or nonalcoholic drinks and to show less evidence of employees drinking on the job than control establishments, but they were also more likely to serve pitchers of beer or mixed drinks. These findings are tentative because of the small sample sizes. In addition, checking IDs of patrons under 30 was observed at only 14 treatment establishments (9 percent) and 14 control establishments (18 percent), a nonsignificant difference.

Discussion

Questionnaire data indicated that the training program had a positive impact on improving knowledge and beliefs. Observational data collected 4 to 6 weeks after training about the effectiveness of the training program were inconclusive given the small sample sizes and design limitations of the study. Diffusion of training from treatment to control conditions, while unlikely, cannot be completely ruled out; neither can preexisting differences between conditions, although matching on establishment type and size should have increased the comparability between conditions.

Overall, the observations seemed to indicate relatively little impact of the training program on server behavior but did show a tendency for the treatment establishments to engage in more responsible practices than control establishments. Although tentative, these findings suggest that other programs may want to incorporate training on policy issues in addition to server-intervention training.

Responsible alcohol-service programs should consider offering programs in the working environments of managers and servers to better convince staff of the benefits of responsible alcohol-service practices. On-site, tailored feedback on appropriate practices might provide more potent training and a better diagnosis of establishment features that create barriers to responsible alcohol service.[9]

Furthermore, one-on-one training with managers, including follow-up support, may be needed to encourage establishments to develop policies and to help them overcome obstacles to implementation. In the current study, some managers may not have had the authority or support to implement new policies. Previous research suggests that before responsible alcohol-service practices can become fully institutionalized, support at all levels must be obtained.[5,9]

State and local regulations also can do more to encourage responsible alcohol-service practices. States that mandate training could require documentation of changes in policy and server behavior to encourage implementation of responsible practices. Regulations banning practices such as happy hours and serving doubles should be combined with educational strategies to convince establishments that practicing responsible alcohol service will not put them at an unfair competitive advantage or adversely affect customer volume and tips. Future research on the role drinking establishments can play in reducing alcohol-related problems should continue to focus on comprehensive strategies including government regulation, establishment policies, and server behavior. ☐

Acknowledgments

This research was supported in part by grants from the Henry J. Kaiser Family Foundation of Menlo Park, the Pew Memorial Trust of Philadelphia, the Robert Wood Johnson Foundation of Princeton, and the Stuart Foundation of San Francisco. The authors thank Stephen P. Fortmann, MD, two anonymous reviewers, and the editor for their comments on an earlier version of this manuscript.

Increased Risk of Ectopic Pregnancy with Maternal Cigarette Smoking

ABSTRACT

As part of a case-control study of ectopic pregnancy, we evaluated the potential etiologic role of cigarette smoking. Maternal cigarette smoking at the time of conception was associated with an increased risk of ectopic pregnancy with a dose-response relationship (adjusted odds ratios: 1.30 to 2.49). On the other hand, partner's smoking was not associated with ectopic pregnancy. The study provides a supplementary argument towards a causal effect of smoking in the development of ectopic pregnancy. Introduction

During the past two decades, the incidence of ectopic pregnancy has doubled or tripled in many parts of the world.[1] It currently constitutes 1.2 to 1.4 percent of all reported pregnancies[1], and remains the leading cause of maternal death during the first trimester of pregnancy in industrial countries.[2] The main identified risk factors are pelvic inflammatory disease (PID) and sexually transmitted diseases (STDs), previous ectopic pregnancies, pelvic surgery, previous use of intrauterine device (IUD), and oral contraceptives and IUD use at the time of conception.[1] Several studies have shown a positive association with cigarette smoking.[3–8] In most of them, smoking was not the primary hypothesis and the precise quantity of cigarette smoked was not investigated. Furthermore, some important confounding factors (e.g., STDs) were not taken into account.

As part of a case-control study of ectopic pregnancy, we further investigated the potential etiologic relationship between cigarette smoking, correcting for the above deficiencies wherever possible.

Methods

A case-control study was conducted during 1988 in seven large maternity hospitals in the Paris area (France). The cases were women ages 15–44 years, whose diagnosis had been confirmed by coelioscopy or laparotomy (n = 279). For each case, the first woman who delivered in the same center following the operation of the index-case was eligible as a control. When the woman selected as a control refused to be interviewed (n = 7), the woman immediately following who delivered in the same center was taken instead.

The interview collected standardized information on reproductive history, birth control practices history, sexual history, medical history including STDs and PID,
